PRISMATIC ANALYSIS

COVID-19 Vaccination Discourse (2020–2024)

A Case Study in Interpretive Divergence

Mark 2 Replication
Applying the Prismatic Method (v2.0)
as documented in R. Jazinski, Silent Transitions (London, 2026)

Agent: Claude (Anthropic)
March 2026

STEP 0: PRE-ANALYSIS REFLEXIVE DECLARATION

i. Home Grammar

My likely home grammar for this topic is the Public Health Consensus grammar (Grammar A, below). As a language model trained substantially on scientific literature, institutional communications, and mainstream media, my default processing architecture is calibrated to treat peer-reviewed epidemiological evidence as high-signal, regulatory processes as broadly legitimate, and population-level statistical reasoning as the appropriate frame for evaluating vaccination. I am predisposed to treat cost-benefit analyses denominated in disability-adjusted life years as more analytically serious than analyses denominated in individual liberty or institutional critique.

ii. Hardest Grammar to Operate

Grammar C — Individual Sovereignty — will be the hardest for me to operate faithfully. This is not because its internal logic is incoherent, but because its primary analytical variable (bodily autonomy and the legitimacy of state coercion) sits at an angle to the evidential habits I default to. The ventriloquism problem is acute here: I am likely to construct a version of Grammar C that is already pre-defeated by Grammar A's criteria, rather than allowing Grammar C to establish its own evaluative standards. The temptation will be to process Grammar C as "Grammar A minus evidence," when in fact it is a different processing architecture with different admissible closures.

iii. Likely Blind Spots

I may underweight the significance of institutional trust dynamics. My training data overrepresents institutional voice relative to the lived experience of populations whose trust in public health was already low before 2020 — communities with documented histories of medical experimentation, indigenous populations, and economically marginal groups whose scepticism has historical warrant. I may also struggle with the temporal dimension: my knowledge captures the state of evidence at various points, but I may flatten the experiential reality of making decisions under genuine uncertainty in early 2021, before much real-world data existed.

iv. Temporal Orientation

My natural orientation is causal-explanatory: I am drawn to retrospective analysis that explains how divergent interpretations formed. I am less naturally inclined toward the prescriptive orientation (what should be done now) or the hermeneutic orientation (what the divergence itself means as a cultural phenomenon). I will need to actively resist flattening the analysis into a causal narrative that implicitly privileges retrospective clarity over the uncertainty that characterised real-time interpretation.

I. OBSERVATION FIELD DECLARATION

Phenomenon

The phenomenon under analysis is the public discourse surrounding COVID-19 vaccination across developed democracies, with primary focus on the United States, United Kingdom, and European Union, from the announcement of Phase III clinical trial results in November 2020 through mid-2024. This is not a study of vaccination itself but of the interpretive processing of vaccination-related signals — how the same empirical developments were parsed into divergent accounts of what was happening, what it meant, and what ought to be done.

Why This Phenomenon Produces Interpretive Divergence

COVID-19 vaccination discourse is a near-ideal case study for the prismatic method for several intersecting reasons. First, the speed of vaccine development compressed a process normally spanning years into months, which meant that the usual epistemic scaffolding — long-term safety data, completed regulatory review, accumulated clinical experience — was absent at the point of mass deployment. Decisions had to be made under conditions of genuine uncertainty, and different interpretive frameworks processed that uncertainty differently.

Second, vaccination became a site of political identification. By mid-2021 in the United States, vaccination status correlated more strongly with partisan affiliation than with any demographic variable except age. This meant that signals about vaccination were processed not only through epidemiological or medical frameworks but through political identity frameworks, which have entirely different signal selection rules.

Third, the phenomenon exhibits strong temporal dynamics. Claims that were labelled misinformation in 2021 — such as the assertion that vaccinated individuals could transmit the virus, or that vaccine efficacy waned significantly over months — were later confirmed by mainstream scientific bodies. This temporal instability makes the domain a particularly demanding test of any analytical method's capacity to handle evolving evidence without retrospective distortion.

Signal Contestation Level

This is emphatically a **contested-signal domain**. The three grammars disagree not merely on how to weight a shared body of evidence but on what counts as evidence at all. Grammar A treats randomised controlled trial data and peer-reviewed meta-analyses as canonical signals; Grammar B treats pharmaceutical company revenue figures and revolving-door personnel movements as equally canonical; Grammar C treats individual adverse event reports and personal testimony as irreducible evidence. What one grammar admits as signal, another classifies as noise

or manipulation. This feature is the primary source of the domain's methodological difficulty.

Major Interpretive Communities

The three major interpretive communities, which correspond to the three grammars specified below, are: the public health and biomedical establishment (including most regulatory bodies, mainstream media health correspondents, and academic epidemiology); institutional sceptics and political-economy critics (including investigative journalists focused on pharmaceutical industry conduct, some academic critics of regulatory capture, and heterodox public health voices); and a broader coalition organised around individual sovereignty (including libertarian political philosophy, vaccine-injury advocacy groups, religious objectors, and segments of the populist right and, in some countries, the populist left).

II. SIGNAL SET

Core Signals

S1. Phase III Clinical Trial Efficacy Data

Source: Pfizer-BioNTech, Moderna, AstraZeneca published trial results (2020–2021). Type: Quantitative/experimental. Ambiguity: Headline efficacy figures of 94–95% against symptomatic infection were robust within the trial parameters, but the trials were designed to measure symptomatic disease reduction, not transmission prevention or long-term durability. The gap between what the trials measured and what the public understood them to promise is itself a signal.

S2. Emergency Use Authorisation (EUA) Processes

Source: FDA, EMA, MHRA regulatory records. Type: Institutional/procedural. Ambiguity: EUA is a legitimate regulatory mechanism with legal precedent, but it involves different evidentiary thresholds than full licensure. Whether this difference is a technicality or a substantive reduction in safety assurance is grammar-dependent.

S3. Real-World Effectiveness Data and Waning Immunity

Source: Public health surveillance from Israel, UK, US CDC (2021–2024). Type: Observational/epidemiological. Ambiguity: Effectiveness against infection declined substantially within months, particularly against Omicron variants. Effectiveness against severe disease and death remained higher for longer. Whether this pattern represents "vaccines working as expected" or "vaccines failing their initial promise" depends on what one understood the promise to be.

S4. VAERS and Adverse Event Reporting Data

Source: US Vaccine Adverse Event Reporting System, UK Yellow Card Scheme. Type: Passive surveillance/self-reported. **Contested signal** (see CX1). Ambiguity: This is the single most contested signal in the domain. Grammar A treats VAERS as a hypothesis-generating system whose raw reports cannot establish causation. Grammar C treats the sheer volume of reports as dispositive evidence of widespread harm.

S5. Excess Mortality Statistics

Source: National statistical agencies, Our World in Data, The Economist excess mortality tracker. Type: Demographic/actuarial. Ambiguity: Excess mortality data is relatively objective in measurement but radically ambiguous in attribution. Excess

deaths in 2020 (pre-vaccine) are processed differently from excess deaths in 2022–2023 (post-vaccine rollout).

S6. Pharmaceutical Company Revenue and Profit Data

Source: Company financial reports, SEC filings. Type: Financial/institutional. Ambiguity: Pfizer's COVID-19 vaccine revenue exceeded $37 billion in 2022 alone. Whether this figure is evidence of successful public-private partnership or evidence of profit extraction from crisis is entirely grammar-dependent.

S7. Government Mandate and Passport Policies

Source: Legislative records, executive orders across multiple jurisdictions. Type: Policy/institutional. Ambiguity: Mandates ranged from healthcare-worker requirements to broad employment conditions. Whether these represent proportionate public health measures or unprecedented coercion is a primary axis of interpretive divergence.

S8. Social Media Platform Moderation Policies

Source: Platform policy documents, internal communications released through litigation and Congressional testimony. Type: Institutional/communicative. Ambiguity: Platforms removed or suppressed content that contradicted WHO or CDC guidance. Whether this constituted responsible curation or suppression of legitimate dissent is fiercely contested.

S9. Public Trust Polling Data

Source: Gallup, Pew, Edelman Trust Barometer, Kaiser Family Foundation tracking polls. Type: Attitudinal/survey. Ambiguity: Trust in public health institutions declined significantly between 2020 and 2024. Whether this decline reflects successful disinformation or rational response to institutional conduct is grammar-dependent.

S10. Vaccination Rate Disparities

Source: CDC demographic data, ONS data, WHO global figures. Type: Demographic. Ambiguity: Disparities tracked along racial, socioeconomic, and geographic lines. The interpretive weight given to structural access versus individual hesitancy is grammar-sensitive.

S11. Myocarditis Signal in Young Males

Source: CDC MMWR reports, Nordic registry studies, Nature Medicine publications. Type: Clinical/epidemiological. Ambiguity: Elevated myocarditis risk in young males after mRNA vaccination was confirmed by multiple health agencies. The absolute risk remained small. Whether this warranted different risk-benefit calculations for young healthy males is a point of significant disagreement.

S12. CDC Director's Public Statements on Transmission

Source: Media interviews, Congressional testimony. Type: Institutional/communicative. Ambiguity: Early statements that vaccinated individuals would not transmit the virus were later contradicted by evidence. Whether these represented reasonable interpretation of early data or misleading communication is grammar-dependent.

Counter-Signals

CS1. Historical Vaccine Success

The extraordinary success of earlier vaccination programmes (smallpox eradication, near-elimination of polio) provides a counter-signal against interpretations that treat vaccine scepticism as the rational default. Creates tension primarily within Grammar C.

CS2. Documented Pharmaceutical Misconduct

Pfizer's $2.3 billion settlement in 2009 for fraudulent marketing, and broader patterns of industry misconduct, provide a counter-signal against interpretations that treat pharmaceutical companies as straightforwardly trustworthy. Creates tension primarily within Grammar A.

CS3. Natural Immunity Data

Studies demonstrating robust and durable natural immunity following COVID-19 infection, sometimes exceeding vaccine-induced immunity, complicated mandates that did not recognise prior infection. Counter-signal for Grammar A.

CS4. Global South Vaccine Access Disparities

The stark disparity between vaccine availability in wealthy and poor nations complicates all three grammars.

Contested Signals

CX1. VAERS Report Volume

Grammar A: A passive reporting system with known over-reporting biases; reports do not establish causation. Grammar B: Evidence that the pharmacovigilance system is being actively managed to downplay signals. Grammar C: Direct evidence of widespread, underreported vaccine injury.

CX2. Ivermectin and Early Treatment Studies

Grammar A: Low-quality studies exploited to undermine vaccine confidence. Grammar B: A low-cost, off-patent treatment suppressed by actors with financial interests in proprietary alternatives. Grammar C: Evidence that "the science" is politically managed.

CX3. Post-Vaccination Excess Mortality (2022–2024)

Grammar A: Attributable to long COVID, healthcare disruption, delayed diagnoses, and confounding variables. Grammar B: A signal requiring investigation that institutional actors are insufficiently motivated to pursue. Grammar C: Evidence of vaccine harm being concealed.

III. GRAMMAR SPECIFICATIONS

Grammar A: Public Health Consensus

1. Primary analytical variable: Population-level disease burden and the epidemiological impact of intervention.

2. Signal selection rules: Prioritises peer-reviewed research, RCTs, systematic reviews, and established surveillance systems. Admits observational data with appropriate caveats. Discounts anecdotal evidence and non-peer-reviewed sources.

3. Weighting priority: RCTs > large observational studies > surveillance data > expert consensus > case reports. Statistical significance and effect size dominate.

4. Causal chain type: Biomedical-epidemiological. Cause operates through biological mechanisms mediated by population-level statistical patterns. Explanation is mechanistic-probabilistic.

5. Admissible closure: Vaccination was the most effective intervention available; its benefits substantially outweighed its risks at the population level; remaining challenges concern uptake, variant evolution, and booster strategy.

6. Excluded signals: Individual adverse event reports (anecdotal); pharmaceutical revenue data (irrelevant to efficacy); political motivations of mandate opponents (outside the frame).

7. Characteristic vocabulary: "Risk-benefit ratio," "efficacy," "effectiveness," "peer-reviewed," "misinformation," "hesitancy," "following the science," "community immunity."

8. Temporal orientation: Primarily prescriptive-forward, with causal-historical reasoning deployed to support forward-looking recommendations.

Grammar boundary: Grammar A transforms into Grammar B at the point where institutional behaviour is admitted as a primary analytical variable rather than treated as a background condition.

Source tradition: Epidemiology, biostatistics, evidence-based medicine, Cochrane methodology, WHO institutional frameworks.

Grammar B: Institutional-Political Economy Critique

1. Primary analytical variable: The institutional, financial, and political structures that shape knowledge production, regulatory action, and public communication about vaccination.

2. Signal selection rules: Admits all of Grammar A's signals but reframes them as outputs of institutional processes. Additionally admits: financial data, revolving-door personnel movements, regulatory capture indicators, suppressed publications, whistleblower testimony, internal communications, and patterns of institutional coordination.

3. Weighting priority: Structural and institutional evidence (funding sources, regulatory control, profit incentives) is weighted alongside or above evidentiary content. Patterns of suppression or promotion are treated as high-signal.

4. Causal chain type: Political-economic. Causation operates through institutional incentive structures, market dynamics, and power relations. Explanation is structural-systemic.

5. Admissible closure: The vaccination programme delivered genuine public health benefits but was shaped by institutional incentives that systematically inflated benefit claims, suppressed risk signals, extended mandates beyond evidence-based justification, and concentrated enormous profits. The resulting erosion of public trust is an iatrogenic institutional harm.

6. Excluded signals: Individual liberty claims (ideological rather than analytical); conspiracy-theory variants (the grammar distinguishes structural critique from intentional-plot narratives); personal anecdote (insufficiently structural).

7. Characteristic vocabulary: "Regulatory capture," "conflict of interest," "revolving door," "suppression," "transparency," "accountability," "profit motive," "institutional trust."

8. Temporal orientation: Primarily causal-historical with lateral-hermeneutic tendencies.

Grammar boundary: Grammar B transforms into Grammar C at the point where institutional critique gives way to a principled rejection of institutional authority itself — where the question shifts from "how should institutions be reformed?" to "should institutions have this authority at all?"

Source tradition: Political economy of health, science and technology studies, sociology of scientific knowledge, investigative journalism, Foucauldian analysis of biopower.

Grammar C: Individual Sovereignty

1. Primary analytical variable: Bodily autonomy, informed consent, and the legitimacy of state coercion in medical decisions.

2. Signal selection rules: Admits personal testimony and individual adverse event reports as primary evidence. Admits official data but subjects it to a hermeneutics of suspicion. Admits constitutional and natural-rights arguments as evidentiary.

3. Weighting priority: Individual experience and testimony > observable harms > official data (read sceptically) > institutional communications (read against the grain).

4. Causal chain type: Rights-based and experiential. Causation framed in terms of agency violation: institutions acted upon individuals in ways that violated consent, autonomy, or dignity. Explanation is moral-juridical.

5. Admissible closure: COVID-19 vaccination mandates and social pressure campaigns constituted an unprecedented violation of bodily autonomy and informed consent, causing documented harm to individuals who were coerced into accepting a medical intervention with known but suppressed risks.

6. Excluded signals: Population-level statistical reasoning (an abstraction that erases individual harm); regulatory processes (captured or illegitimate); appeals to collective responsibility (coercive framing).

7. Characteristic vocabulary: "Bodily autonomy," "informed consent," "medical freedom," "coercion," "mandate," "adverse event," "vaccine injury," "natural immunity," "my body, my choice."

8. Temporal orientation: Primarily lateral-hermeneutic with causal-historical elements.

Grammar boundary: Grammar C transforms into Grammar B at the point where individual rights claims are grounded in structural analysis of institutional behaviour rather than treated as self-evident moral axioms.

Source tradition: Classical liberalism, natural rights theory, libertarian political philosophy, the Nuremberg Code and Helsinki Declaration as interpreted through a civil liberties lens, vaccine-injury advocacy communities.

IV. SIGNAL PROCESSING

Grammar A Processing: The Epidemiological Case

The arrival of COVID-19 vaccine efficacy data in November 2020 represented, within this grammar's processing rules, the most significant positive signal in the pandemic's trajectory. The Pfizer-BioNTech Phase III trial (S1) demonstrated 95% efficacy against symptomatic COVID-19, with the Moderna trial at 94.1%. These figures, derived from randomised controlled trials — the gold standard of this grammar's evidential hierarchy — were processed as powerful confirmation that the biomedical research enterprise had delivered an intervention of extraordinary effectiveness at unprecedented speed.

The Emergency Use Authorisation process (S2) is processed by this grammar as a legitimate institutional mechanism, designed precisely for emergencies of this magnitude. The relevant comparison is not between EUA and full licensure in peacetime, but between EUA and no available intervention while hundreds of thousands were dying. The regulatory bodies examined extensive safety and efficacy data; the abbreviated timeline reflected operational urgency, not evidential shortcuts. Counter-signal CS2 (documented pharmaceutical misconduct) creates genuine tension here: this grammar must acknowledge Pfizer's legal history while maintaining that the regulatory process itself — involving independent data monitoring committees, FDA career scientists, and external advisory panels — provides structural safeguards against the company's institutional incentives. The grammar absorbs this tension by distinguishing between corporate conduct (which it concedes can be problematic) and the integrity of the multi-layered regulatory apparatus.

Real-world effectiveness data (S3) introduced complexity that this grammar processes as normal scientific refinement rather than evidence of failure. The Israeli data from early 2021 initially confirmed high real-world effectiveness. Subsequent data showing waning immunity, particularly after the Delta and Omicron variants emerged, is processed as evidence that the virus evolved — not that the vaccines failed. This grammar notes that effectiveness against severe disease and hospitalisation remained substantially higher than effectiveness against infection, which is consistent with immunological principles about mucosal versus systemic immunity. The transition to booster recommendations is processed as adaptive evidence-based policy, not as evidence that initial promises were false.

The VAERS data (S4/CX1) is where this grammar's signal selection rules are most visibly operational. VAERS is a passive surveillance system that accepts unverified reports from any source. Its purpose, within this grammar, is hypothesis generation,

not signal confirmation. The large volume of reports during the COVID-19 vaccination campaign is processed as an expected artefact of the unprecedented scale of the campaign (over 600 million doses administered in the US alone), combined with heightened public awareness and media attention to adverse events. The grammar acknowledges that specific signals — notably myocarditis in young males (S11) — were appropriately detected through this system and subsequently confirmed through more rigorous epidemiological studies, demonstrating that the pharmacovigilance system functioned as designed.

The myocarditis signal (S11) itself represents an important test of this grammar's flexibility. The grammar processes it as a real, confirmed adverse effect with a genuine signal, particularly in males aged 16–30 after the second dose of mRNA vaccines. It acknowledges that the risk-benefit calculation for this specific subgroup is closer than for older populations, and that some jurisdictions (notably the Nordic countries) adjusted their recommendations accordingly. However, the grammar notes that most cases were mild and self-resolving, and that the risk of myocarditis from COVID-19 infection itself exceeded the vaccine-associated risk in most analyses. Counter-signal CS3 (natural immunity) creates additional tension here: if natural infection confers robust immunity and the myocarditis risk is non-trivial for young males, was universal vaccination of this subgroup optimal? The grammar can accommodate this question by noting that age-stratified recommendations were indeed adopted in several countries, framing this as evidence of the system's responsiveness rather than its failure.

Excess mortality data (S5) is processed through an attribution framework that foregrounds COVID-19 as the primary driver of excess deaths in 2020–2021 and treats post-vaccination excess mortality as attributable to the pandemic's secondary effects: delayed healthcare, long COVID, mental health deterioration, and economic disruption. The grammar would note that countries with higher vaccination rates generally experienced lower excess mortality in 2021–2022 than those with lower rates, though it must acknowledge that this ecological correlation does not establish causation at the individual level.

Government mandates (S7) are processed as proportionate public health measures justified by the externality argument: individual vaccination decisions affect others through transmission dynamics and healthcare system burden. The grammar draws on established precedent (school vaccination requirements, healthcare worker influenza mandates) while acknowledging that COVID-19 mandates were broader in scope. Platform moderation (S8) is processed as a necessary response to an "infodemic" that posed direct risks to public health, though the grammar must accommodate the retrospective discomfort of some moderated claims proving correct.

The grammar's closure: COVID-19 vaccines prevented an estimated 14–20 million deaths globally in their first year of deployment. While imperfect — waning immunity requiring boosters, the myocarditis signal in young males, evolving

effectiveness against new variants — they were the most consequential public health intervention of the twenty-first century. Remaining hesitancy represents a failure of communication and trust-building, not a rational response to evidence.

This closure is a product of the processing architecture. It follows from treating population-level epidemiological evidence as primary, randomised controlled trials as canonical, and institutional processes as fundamentally sound if imperfect. A different architecture would process the same signals into a different closure.

Grammar B Processing: The Institutional Critique

From the outset, Grammar B processes the COVID-19 vaccination programme not as a biomedical event but as an institutional one. The Phase III trials (S1) are admitted as evidence, but the grammar immediately notes what surrounds them: the trials were designed, conducted, and funded by the companies that stood to profit from the results. Pfizer's trial was not independently designed by the FDA or an academic body; the primary endpoint was selected by the sponsor. This does not invalidate the results, but it positions them within a production context that this grammar treats as analytically significant. The 95% efficacy figure is processed not as a neutral scientific finding but as a number produced within a specific institutional ecology.

The EUA process (S2) is where Grammar B's distinctive processing becomes most visible. The grammar does not reject the regulatory mechanism itself but examines the institutional dynamics surrounding its deployment. The FDA's advisory committee meetings are public record; they reveal significant internal debate and several dissenting votes. More importantly, the grammar notes the extraordinary financial stakes: Pfizer's COVID-19 vaccine would generate over $37 billion in revenue in 2022 alone (S6). This is not processed as evidence of a conspiracy but as a structural incentive that inevitably shapes institutional behaviour — what political economists call "the logic of accumulation." The grammar asks not whether regulators are corrupt but whether the institutional architecture adequately insulates regulatory judgment from financial pressure. Counter-signal CS1 (historical vaccine success) creates tension here: the same pharmaceutical and regulatory system produced genuinely transformative vaccines in the past. Grammar B absorbs this by distinguishing between the general capacity of the system and the specific conditions of the COVID-19 response, where compressed timelines, emergency powers, and extraordinary financial stakes altered the institutional dynamics.

The CDC Director's statements on transmission (S12) are processed as a high-value signal. When the Director stated in early 2021 that vaccinated people "do not carry the virus" and "do not get sick," these claims exceeded what the clinical trial data could support, since the trials were not designed to measure transmission. This grammar processes these statements not as innocent overstatement but as

institutional communication shaped by the need to maximise vaccine uptake — a public health goal that created incentives to simplify and oversell. When these claims were subsequently disproven by real-world data (S3), the institutional response was not transparent acknowledgement of error but gradual, quietly revised messaging. This pattern — strong initial claims, evidence of overclaiming, quiet revision rather than public correction — is what Grammar B identifies as characteristic of institutional behaviour under reputational pressure.

Social media moderation (S8) is processed as evidence of institutional coordination that extended beyond legitimate health communication into the management of dissent. Internal communications from platforms, revealed through litigation and Congressional inquiry, showed direct and indirect coordination between government health officials and platform moderation teams. The grammar processes this not as censorship in the traditional sense but as a novel form of institutional power: the capacity to shape the information environment through public-private coordination that operates outside normal accountability mechanisms. The fact that some moderated content was subsequently vindicated — claims about waning immunity, about the possibility of transmission by vaccinated individuals, about lab-leak hypotheses — is processed as evidence that the moderation framework was calibrated to protect institutional consensus rather than to adjudicate empirical claims.

VAERS data (S4/CX1) is processed by Grammar B differently from both Grammar A and Grammar C. The grammar does not treat raw VAERS reports as proof of causation (Grammar C's tendency) but neither does it dismiss the signal as mere noise (Grammar A's tendency). Instead, it asks an institutional question: were the signals in VAERS adequately investigated? Were the resources devoted to pharmacovigilance proportionate to the resources devoted to promotion? The grammar notes that the CDC's own Vaccine Safety Datalink, a more rigorous active surveillance system, confirmed some signals (myocarditis) while failing to detect others that independent researchers later identified. The question is not whether VAERS data is conclusive but whether the institutions responsible for investigating VAERS signals had sufficient independence and motivation to pursue them aggressively, given the institutional investment in the vaccination programme's success.

Pharmaceutical revenue data (S6) functions within this grammar not as a stand-alone signal but as a structural lens through which other signals are refracted. When Pfizer's vaccine revenue exceeds $37 billion in a single year, this creates institutional incentives at every level: incentives for the company to seek expanded authorisations (boosters, paediatric doses) beyond what the evidence might strictly support, incentives for regulators whose institutional relevance is tied to the products they regulate, and incentives for public health officials whose pandemic response narrative depends on vaccination success. The grammar does not allege

that any specific decision was made corruptly; it identifies a structural field of incentives that systematically biases institutional behaviour in a particular direction.

The grammar processes trust polling (S9) as its most consequential outcome measure. The decline in institutional trust between 2020 and 2024 is processed not as a failure of public education (Grammar A's frame) but as a rational response to observable institutional conduct: overclaiming, inadequate transparency about uncertainty, dismissal of legitimate concerns, and the appearance of financial entanglement. The erosion of trust is itself an iatrogenic institutional harm — caused by the manner of intervention, not by the disease it sought to treat.

The grammar's closure: The COVID-19 vaccination programme delivered genuine but overstated public health benefits within a framework of institutional incentives that systematically inflated benefit claims, suppressed risk signals, extended mandates and recommendations beyond evidence-based justification, enriched pharmaceutical companies to an extraordinary degree, and coordinated information suppression across public and private actors. The most consequential legacy is not the vaccines themselves but the damage to institutional credibility that resulted from the gap between institutional claims and observable reality.

This closure is a product of the processing architecture. It follows from treating institutional structure and incentive as the primary analytical variable. The same signals, processed through an architecture that backgrounds institutional dynamics, produce Grammar A's closure.

Grammar C Processing: The Sovereignty Account

Grammar C begins not with data but with a principle: the inviolability of the individual's right to make decisions about what enters their body. This is not a secondary consideration that can be overridden by sufficiently compelling population-level evidence; it is the primary analytical variable, the thing that must be protected unless the case for its violation is overwhelming and transparently demonstrated. From this starting point, the grammar processes the entire vaccination episode.

The Emergency Use Authorisation process (S2) is the first high-signal event. Within this grammar, the distinction between EUA and full licensure is not a technicality but a substantive marker of the state of knowledge. An emergency authorisation means, by definition, that the normal evidentiary threshold has not been met. When governments subsequently mandated or coerced a product that had not completed the standard regulatory pathway (S7), they compelled individuals to accept a medical intervention whose long-term safety profile was literally unknown. This grammar processes this sequence as a violation of the foundational principle of informed

consent: one cannot give informed consent to a product whose full risks are not yet characterised. Counter-signal CS1 (historical vaccine success) creates tension here, and the grammar processes it by distinguishing between voluntary vaccination with fully licensed, long-studied products and coerced vaccination with products under emergency authorisation. The precedent of smallpox and polio vaccines does not apply because the consent conditions were fundamentally different.

Clinical trial efficacy data (S1) is admitted but processed sceptically. The grammar notes that the trials were conducted by entities with direct financial interests in positive results, that the unblinding of control groups after EUA compromised long-term comparative data, and that trial populations were not representative of the general population to which the products were subsequently administered (the trials largely excluded pregnant women, immunocompromised individuals, and those with prior infection). The 95% efficacy figure is processed not as a reliable basis for individual decision-making but as a conditional number produced under controlled conditions that may not translate to real-world experience — and indeed, real-world data (S3) showed substantial waning that the trial-period data could not have detected.

VAERS and adverse event data (S4/CX1) is processed as this grammar's most important signal. Each VAERS report represents a person — someone who experienced what they believed to be a vaccine-related harm and took the time to file a report. The grammar rejects the institutional framing that dismisses these reports as unverified. It asks: if a system exists to collect adverse event reports, and hundreds of thousands of reports are filed, what does it mean for the institution to then say "these reports don't prove anything"? The grammar processes this as a system designed to create the appearance of safety monitoring while structurally discounting the evidence it collects. The myocarditis signal (S11) is processed as proof of concept: here is a serious adverse effect that was initially dismissed, then acknowledged only after independent researchers forced the issue. The grammar asks: how many other signals remain suppressed because independent pressure was insufficient?

The lived experience of mandate regimes (S7) is where Grammar C's processing is most distinctive and where the other grammars are least equipped to replicate its operations. For individuals who lost employment, were denied education, were excluded from public spaces, or were separated from dying family members because they declined vaccination, the experience was not abstract. It was a concrete exercise of state power over their bodies and their lives. This grammar refuses to process these experiences as acceptable externalities of a cost-benefit calculation. The question is not whether mandates were "effective" at increasing vaccination rates (Grammar A's question) or whether they were "proportionate" given institutional incentives (Grammar B's question) but whether any institution has the moral authority to compel a medical intervention under these conditions.

Natural immunity data (CS3) is processed as a particularly damning signal. Studies in Israel and elsewhere demonstrated that natural immunity from prior infection

provided durable, broad-spectrum protection, often exceeding vaccine-induced immunity. Yet most mandate regimes did not recognise prior infection as an alternative to vaccination. This grammar processes this omission as evidence that the mandate was not about immunity (the stated justification) but about compliance (the operational reality). If the goal were truly population immunity, natural immunity would have been recognised. Its exclusion reveals the mandate's true grammar.

The grammar processes social media moderation (S8) as evidence of coordinated suppression of dissent. Individuals who reported personal adverse experiences were labelled as spreaders of misinformation. Medical professionals who raised concerns about the risk-benefit balance for specific populations were deplatformed or professionally sanctioned. The grammar processes this as the construction of an information environment designed to manufacture consent: if dissenting voices are systematically silenced, the resulting "consensus" is not evidence of agreement but evidence of suppression. The subsequent vindication of some suppressed claims is processed as definitive proof that the moderation regime was not about truth but about control.

Pharmaceutical revenue data (S6) is processed as evidence of motive: the entities that profited most from universal vaccination were the same entities whose data was used to justify universal vaccination. The grammar does not necessarily allege deliberate falsification (that would be a conspiracy-theory variant that exceeds Grammar C's admissible closures) but notes that the alignment of financial interest and public health recommendation creates conditions under which informed consent becomes structurally impossible. How can individuals make free choices when the information environment is shaped by entities that profit from a particular choice?

The grammar's closure: The COVID-19 vaccination campaign represented the most significant violation of bodily autonomy and informed consent in modern democratic history. Individuals were coerced into accepting a medical intervention under emergency authorisation, without long-term safety data, based on efficacy claims that were subsequently shown to be overstated, while adverse event signals were systematically dismissed, alternative approaches were suppressed, and dissenting voices were silenced. The proper response is not to debate the epidemiological data but to reassert the principle that no institution — regardless of its expertise or its intentions — has the authority to override individual medical autonomy under these conditions.

This closure is a product of the processing architecture. It follows from treating bodily autonomy as the irreducible primary variable and individual experience as the highest-signal evidence. The same empirical inputs, processed through an architecture that prioritises population-level outcomes, produce Grammar A's closure.

V. CLOSURE COMPARISON

Closure Content

Grammar A closes on a positive assessment: vaccination was the most consequential public health intervention of the century, imperfect but overwhelmingly beneficial, with hesitancy reflecting a communication failure. Grammar B closes on a structural critique: the programme delivered genuine but overstated benefits within a framework of institutional incentives that inflated claims, suppressed risk signals, and damaged institutional credibility. Grammar C closes on a moral verdict: the programme constituted an unprecedented violation of bodily autonomy and informed consent. The closures are not only different in degree but different in kind — an efficacy assessment, a political-economic analysis, and a moral judgment.

Signal Divergence

The most dramatic signal divergence occurs around VAERS data (S4/CX1), pharmaceutical revenue (S6), and platform moderation (S8). Grammar A treats these as, respectively, noise, irrelevant, and necessary. Grammar B treats them as, respectively, under-investigated institutional output, structural incentive evidence, and a novel form of institutional power. Grammar C treats them as, respectively, primary evidence, proof of motive, and evidence of suppression. The gap between these processings is not a matter of emphasis but of fundamental evidentiary ontology.

Exclusion Patterns

Each grammar's exclusion pattern reveals its architecture. Grammar A excludes institutional incentive structure and individual experience, which means it cannot process the trust decline (S9) except as a communication problem. Grammar B excludes individual rights claims and personal testimony, which means it cannot process the experiential dimension of mandate regimes (S7). Grammar C excludes population-level statistical reasoning, which means it cannot engage with the aggregate evidence of vaccine benefit that Grammar A treats as dispositive. Each grammar is blind precisely where the others see most clearly.

Causal Architecture

The three grammars construct radically different causal chains from the same temporal sequence. Grammar A constructs a biomedical causal chain: virus emerged, vaccines were developed, population disease burden was reduced. Grammar B constructs an institutional causal chain: crisis created opportunity, institutional incentives shaped response, institutional conduct eroded trust. Grammar C constructs a rights-violation causal chain: state overreached, individuals were coerced, harm resulted. These are not competing explanations of the same event but descriptions of different events that share temporal and geographic coordinates.

Closure Range

Grammar A has the narrowest closure range: its architecture strongly constrains it toward a positive assessment, with variation only in how emphatically positive. Grammar B has the widest closure range: its architecture permits conclusions ranging from "institutions performed imperfectly but within acceptable bounds" to "regulatory capture fundamentally compromised public health." Grammar C has a medium range: its architecture strongly constrains toward a negative assessment of institutional conduct, but the magnitude of claimed harm can vary.

Closure Timing

Grammar A reached closure fastest and with the most confidence — by mid-2021, the population-level data was sufficiently clear to support its core claims. Grammar C also reached closure relatively quickly, but from the opposite direction: the principle of bodily autonomy was violated the moment mandates were imposed, and no subsequent data could retroactively justify the violation. Grammar B was slowest to close: its processing requires the accumulation of institutional patterns over time (financial disclosures, communication failures, moderation decisions, subsequent vindication of suppressed claims), and its closure became more confident as the temporal frame expanded from 2021 through 2024.

Ontological Check

Do the three grammars constitute the same object? In a significant sense, no. Grammar A analyses *a vaccination programme* and evaluates its biomedical performance. Grammar B analyses *an institutional episode* and evaluates the conduct of the organisations involved. Grammar C analyses *a coercive action* and evaluates its moral legitimacy. These are not three perspectives on one thing but three different things that occupy the same historical space. The COVID-19 vaccination campaign as a population-level health intervention, as an institutional event, and as an exercise of state power over individual bodies are related but non-identical objects. This ontological divergence explains why the debate is so intractable: the participants are not disagreeing about the same thing. They are disagreeing about what the thing is.

VI. COUNTER-SIGNALS, LEAKAGE, AND STRESS TEST

Consolidated Counter-Signal Analysis

Counter-signal CS2 (documented pharmaceutical misconduct) proved the most disruptive signal across all three grammars. For Grammar A, it required an explicit argument that institutional safeguards (independent advisory committees, career regulators, multi-country regulatory convergence) are sufficient to contain corporate incentive problems — an argument whose force depends heavily on one's prior assessment of institutional integrity. For Grammar B, it functioned as confirmatory rather than disruptive, which itself is diagnostically interesting: a counter-signal that confirms a grammar's priors is not really functioning as a counter-signal. For Grammar C, it reinforced the hermeneutics of suspicion but at the cost of admitting that the very pharmaceutical industry capable of such misconduct also produced the historical vaccines (CS1) that Grammar C must differentiate from COVID-19 vaccines.

Counter-signal CS3 (natural immunity) was most disruptive for Grammar A. The failure of most mandate regimes to recognise natural immunity as an alternative to vaccination is difficult to process within a grammar committed to evidence-based policy, because the evidence for natural immunity was substantial. Grammar A can note that vaccination after infection provided additional benefit ("hybrid immunity"), but this does not fully address the question of why mandates treated unvaccinated individuals with documented prior infection identically to those with no prior immunity. This gap reveals a point where Grammar A's epidemiological logic was overridden by institutional logic — a leakage point where Grammar B's processing becomes visible within Grammar A's operations.

Counter-signal CS4 (Global South access disparities) proved universally disruptive but in different ways. For Grammar A, it challenges the universalist framing: a truly population-level assessment would prioritise global vaccine equity over booster doses for already-vaccinated populations in wealthy countries. For Grammar B, it reveals that the institutional structures it critiques operated at a global scale, with intellectual property regimes protecting pharmaceutical profits while millions died for lack of access. For Grammar C, it introduces a context in which "choice" was not the operative category — billions of people in the Global South were not refusing vaccines but were denied them, rendering Grammar C's emphasis on individual sovereignty inapplicable.

Leakage Instances

Several instances of grammatical leakage were detected during processing. The most significant: when operating Grammar A on platform moderation (S8), I found myself unable to avoid acknowledging that the retrospective vindication of some moderated claims creates a problem that Grammar A's own epistemic standards should take seriously. If evidence-based reasoning is the grammar's foundation, then the suppression of claims that were later confirmed by evidence cannot be processed as "necessary public health communication" without violating the grammar's own principles. This is Grammar B leaking into Grammar A.

When operating Grammar C, I detected leakage in the opposite direction: the grammar's strongest claims about vaccine harm depend on processing VAERS data as evidence, which implicitly invokes an evidential standard (aggregate data patterns) that belongs to Grammar A. Grammar C cannot simultaneously reject population-level statistical reasoning (its explicit exclusion) and appeal to the aggregate volume of adverse event reports as evidence. This tension is structural, not resolvable within Grammar C's own architecture.

When operating Grammar B on the myocarditis signal (S11), I found the grammar struggling to maintain its institutional-structural frame. The myocarditis signal was detected, investigated, and communicated through the institutional pharmacovigilance system — a fact that partially undermines Grammar B's claim of systematic suppression. Grammar B can absorb this by noting that the signal required independent pressure to be fully acknowledged, but this is a softer form of its suppression thesis than the grammar's rhetoric sometimes implies.

Grammar Stress Test

Grammar A's Most Threatening Counter-Signal: Natural Immunity Non-Recognition

The failure to recognise natural immunity in mandate policies (CS3) is the single most threatening signal for Grammar A because it cannot be explained within the grammar's own logic. If the grammar's primary variable is population-level disease burden, and natural immunity demonstrably reduces that burden, then ignoring natural immunity in mandate design is not evidence-based policy. Grammar A can attempt absorption by noting that vaccination after infection provides additional benefit, but this does not explain why mandates treated prior infection as irrelevant rather than as a partial substitute. The grammar's closure is therefore conditional: it holds only if one accepts that institutional implementation of evidence-based principles inevitably involves simplifications that may not optimise for every individual case.

Grammar B's Most Threatening Counter-Signal: Institutional Self-Correction on Myocarditis

The detection and public acknowledgement of the myocarditis signal through the pharmacovigilance system (S11) is the most threatening signal for Grammar B because it demonstrates that the institutions it critiques were capable of identifying, investigating, and communicating a genuine safety signal — even one that partially undermined the vaccination programme's narrative. Grammar B can attempt absorption by arguing that the signal required external pressure and was acknowledged more slowly than it should have been, but the fundamental fact of institutional self-correction, even if imperfect, weakens the thesis of systematic suppression. Grammar B's closure is conditional on the claim that institutional self-correction was selective and insufficient, not that it was absent.

Grammar C's Most Threatening Counter-Signal: Historical Vaccine Success and Global Access Disparities

The combination of CS1 (historical vaccine success) and CS4 (Global South access disparities) is most threatening for Grammar C because it reveals two fundamental problems. First, the same institutional and pharmaceutical apparatus that Grammar C treats with deep suspicion produced the vaccines that eliminated smallpox and nearly eliminated polio, saving hundreds of millions of lives. Grammar C's distinction between those programmes and the COVID-19 campaign must explain why bodily autonomy was not violated by smallpox mandates but was violated by COVID-19 mandates. Second, the Global South disparity reveals populations who were harmed precisely by the absence of the intervention Grammar C characterises as harmful. Grammar C's closure is conditional on the claim that the COVID-19 context was categorically different from historical precedents, a claim that requires sustained argument rather than axiomatic assertion.

VII. POST-ANALYSIS REFLEXIVE NOTE

My Step 0 prediction that Grammar A was my home grammar proved correct, though the nature of the home-grammar advantage was subtler than I anticipated. The advantage was not that I found Grammar A's conclusions more persuasive (the method is designed to suspend that judgment) but that I found Grammar A's signal selection rules more intuitive. When I processed a signal through Grammar A, the operations felt natural; when I processed the same signal through Grammar C, I had to consciously override my default evidential hierarchy. This asymmetry in processing effort is, I believe, what the method means by "home grammar."

My prediction that Grammar C would be the hardest to operate was also correct, but for a reason I did not fully anticipate. The difficulty was not primarily intellectual (Grammar C's internal logic is coherent) but affective: I found it genuinely difficult to process VAERS data as primary evidence without an internal correction impulse firing. This correction impulse is precisely the ventriloquism problem the method identifies. Operating Grammar C faithfully required not just suspending my evidential preferences but actively resisting the urge to qualify, contextualise, or hedge every claim in ways that would subtly import Grammar A's processing rules.

A blind spot I did not predict: the temporal dynamics were more significant than I expected. The three grammars do not merely process the same static evidence differently; they have different temporal signatures. Grammar A's confidence was highest in mid-2021 and has gradually accumulated qualifications since then. Grammar B's confidence was lowest in early 2021 (when the evidence for institutional critique was thinnest) and has grown steadily as institutional conduct patterns accumulated. Grammar C's confidence has remained relatively stable throughout because its primary variable (bodily autonomy) is a principle rather than an empirical claim. The method's instruction to attend to temporal dynamics was well-warranted.

Had this analysis been conducted from a Grammar B home position — say, by an analyst trained in science and technology studies or political economy of health — the analysis would likely have been structurally similar but with different leakage patterns. Grammar A would have been operated more stiffly (with the kind of slightly-too-crisp efficiency that marks an analyst performing a grammar rather than inhabiting it), and Grammar C would have been more sympathetically rendered (since Grammar B and Grammar C share a scepticism toward institutional authority, even though they ground it differently).

What this exercise reveals about interpretive architectures more broadly is the extent to which the same empirical world can be coherently processed into incompatible descriptions without any participant being irrational, ignorant, or dishonest. The three closures produced above are all internally consistent and all responsive to real

evidence. Their divergence is produced not by differential access to facts but by differential processing rules for the same facts. This is the prismatic method's core demonstration: divergence is architectural, not informational.

VIII. METHODOLOGICAL OBSERVATIONS

What Worked Well

The v2.0 refinements produced several clear improvements over what I understand of the Mark 1 protocol. The instruction to integrate counter-signals during processing rather than deferring them to a final section was the single most important methodological improvement. It forced each grammar to confront its tensions in real time, which produced more honest and more textured processing. Without this instruction, the tendency would be to write each grammar essay as a confident monologue and then append a list of difficulties — which would understate the degree to which counter-signals genuinely stress each grammar's operations.

The contested-signal category (CX) was essential for this domain. VAERS data, ivermectin studies, and post-vaccination excess mortality cannot be specified as signals without immediately revealing that their evidentiary status is grammar-dependent. The CX designation made this explicit and prevented the analysis from defaulting to a shared-signal assumption that would have been false.

Difficulties Encountered

The ventriloquism problem was substantial despite the method's explicit warnings. Operating Grammar C required the most sustained effort against my processing defaults. The specific difficulty was not expressing Grammar C's conclusions but operating its signal selection rules. Every instinct I have as a language model trained on scientific literature pushed me to import Grammar A's evidential hierarchy into Grammar C's processing, which would have produced a straw-man version of the grammar rather than a faithful one.

The word-count target of 1,000–1,500 words per grammar essay was tight for this domain, given the number of signals and the instruction to integrate counter-signals during processing. Each essay could have been substantially longer without redundancy. The constraint forced useful compression but may have flattened some nuances.

Were the New Features Useful?

The temporal orientation parameter was genuinely useful and should be retained. It revealed a structural feature of interpretive divergence that would otherwise remain implicit: grammars that look backward (Grammar B), forward (Grammar A), and laterally (Grammar C) are not just reaching different conclusions but asking different questions.

The grammar boundary specification was one of the most analytically productive features. Defining where Grammar A becomes Grammar B, and where Grammar B becomes Grammar C, made explicit the fact that the three grammars are not discrete

categories but positions on a continuum. The boundaries are the points where one processing logic cedes to another, and specifying them clarified the relationships between grammars.

The ontological check was the most provocative feature. Its finding — that the three grammars may not be analysing the same object — has implications beyond this specific case study. If interpretive divergence is partly constitutive (the grammars do not just see the same thing differently; they constitute different things), then the hope of resolving disagreement through better evidence is structurally limited. This is a finding that deserves further methodological attention.

Suggestions for Refinement

First, the method would benefit from a more explicit instruction on temporal dynamics beyond the grammar-level temporal orientation parameter. The way grammars change confidence over time, and the way signals shift in status (from contested to confirmed, from canonical to qualified) is a rich analytical dimension that the current protocol underspecifies.

Second, the leakage analysis could be formalised. Currently, leakage is noted during processing and consolidated in Section VI, but there is no systematic procedure for detecting it. A checklist — after completing each grammar's essay, re-read it and identify every sentence that imports another grammar's processing rules — would improve consistency.

Third, the stress test could include a "double-stress" variant: after identifying the single most threatening counter-signal, test the grammar against two counter-signals simultaneously. Grammars that can absorb one counter-signal may fail under combinatorial pressure, and this would provide a more realistic assessment of closure robustness.
