Prismatic Analysis of COVID-19 Vaccination Discourse (2020–2024)

A Multi-Grammar Interpretive Study Following R. Jazinski (2026)

Section 0: Pre-Analysis Reflexive Declaration

0.1 Home Grammar Identification

My analytical home grammar is Institutional-Scientific Grammar. This grammar privileges peer-reviewed empirical evidence, quantitative measurement, controlled study designs, and institutional validation mechanisms. I recognize this orientation through several markers: my default impulse is to weight randomized controlled trials and large-scale observational studies more heavily than qualitative accounts or individual testimonies; I instinctively seek numerical precision (confidence intervals, effect sizes, p-values) as markers of epistemic reliability; and I tend to frame problems in terms of measurable outcomes (vaccine effectiveness percentages, adverse event rates, uptake statistics) rather than lived experience or structural power relations.

This grammar shapes my signal selection by making me more attentive to signals that arrive through formal publication channels, regulatory databases, and institutional surveys. It inclines me toward closure statements that emphasize aggregate population-level effects and statistical significance over individual variation or systemic critique. I notice that when encountering contested claims, my first move is to ask "what does the peer-reviewed literature say?" rather than "whose interests does this framing serve?" or "what does this feel like for the person experiencing it?"

0.2 Hardest Grammar to Operate

The Critical-Structural Grammar will be most challenging for me to operate authentically. This grammar requires sustained attention to power asymmetries, institutional capture, profit motives, and the ways scientific and policy discourse can serve to legitimize existing hierarchies. Operating this grammar demands that I treat institutional outputs not as neutral knowledge but as artifacts shaped by funding structures, regulatory relationships with industry, and the social position of knowledge producers.

The difficulty is not intellectual—I can articulate critical structural arguments—but dispositional. The Institutional-Scientific Grammar feels like "looking at evidence," while the Critical-Structural Grammar can feel like "imposing a political lens." This reveals the naturalization of my home grammar: it presents itself as neutral observation rather than as one interpretive framework among others. To operate the Critical-Structural Grammar faithfully, I must resist the pull to dismiss structural critiques as "speculation" when they lack the quantitative precision my home grammar privileges, and I must take seriously the possibility that the very architecture of evidence production (what gets studied, how, by whom, with whose funding) is itself a signal rather than a neutral backdrop.

0.3 Anticipated Blind Spots

Blind Spot 1: Individual Phenomenology and Embodied Knowledge
My home grammar's focus on aggregate statistics and population-level effects creates systematic

inattention to individual variation in vaccine response, adverse event experience, and the lived reality of navigating conflicting expert guidance. When someone reports a severe adverse event that doesn't appear in formal safety signals, my home grammar tends to code this as "anecdote" rather than as a data point about surveillance system limitations or the gap between population averages and individual outcomes. I anticipate missing signals about the experiential texture of vaccine injury, the emotional labor of deciding under uncertainty, and the ways aggregate safety data can be simultaneously true at the population level and inadequate for individual risk assessment.

Blind Spot 2: Structural Power and Knowledge Production
I expect to underweight signals about pharmaceutical industry influence on research agendas, regulatory capture, and the ways that funding structures shape which questions get asked and which findings get published. My home grammar treats peer review as a quality filter; the Critical-Structural Grammar treats it as a gatekeeping mechanism that can systematically exclude certain forms of knowledge and certain researchers. I anticipate being slow to recognize signals about conflicts of interest, revolving doors between regulators and industry, and the ways that "evidence-based policy" can serve to depoliticize decisions that are fundamentally about values and power.

Blind Spot 3: Temporal Dynamics of Trust and Institutional Legitimacy
My home grammar tends to treat trust as a dependent variable (people should trust institutions when they produce good evidence) rather than as a complex social process with its own dynamics. I expect to miss signals about how institutional credibility is built and eroded over time, how past betrayals (Tuskegee, opioid crisis, etc.) shape present interpretation, and how the experience of being dismissed or coerced affects future engagement with public health systems. The Institutional-Scientific Grammar sees "vaccine hesitancy" as a knowledge deficit problem; other grammars see it as a rational response to institutional track records.

0.4 Temporal Orientation

My home grammar orients primarily toward the immediate present and near future, with a secondary orientation toward the recent empirical past. The Institutional-Scientific Grammar privileges the most recent data (latest vaccine effectiveness estimates, current variant landscape, newest safety signals) and uses this to make near-term predictions and recommendations. It treats older data as superseded unless it contributes to cumulative knowledge building. This creates a temporal blind spot: insufficient attention to longer historical patterns (history of pharmaceutical scandals, evolution of public health authority, decades-long trends in institutional trust) and to slower-moving structural dynamics (growing wealth inequality, erosion of public institutions, changing media ecosystems).

The Individual-Autonomy Grammar, I anticipate, will orient more strongly toward the immediate present and personal future—the decision I must make now, the risk I face today, the autonomy I exercise in this moment. It has less patience for historical context or population-level long-term trends.

The Critical-Structural Grammar will demand the longest temporal horizon, insisting on situating the 2020–2024 vaccination campaign within decades or centuries of medical colonialism, pharmaceutical capitalism, and the political economy of health. It will be most attentive to how present arrangements reproduce historical patterns and how current decisions shape long-term structural possibilities.

I expect my home grammar's presentism to make me impatient with historical contextualization that the Critical-Structural Grammar requires, and to undervalue the Individual-Autonomy Grammar's focus on the urgency of present decision-making under uncertainty.

Section 1: Observation Field Declaration

1.1 Temporal and Topical Scope

Observation Period: January 2020 – December 2024

Phenomenon Under Analysis: The global discourse surrounding COVID-19 vaccination, encompassing clinical effectiveness data, safety surveillance, policy interventions (mandates, certificates, passports), public trust dynamics, demographic disparities in uptake and hesitancy, information environment shifts, and the interplay between scientific evidence, institutional guidance, and public response.

Geographic Focus: Primarily high-income democracies with robust surveillance systems and documented policy interventions (United States, Canada, European Union member states, United Kingdom, Israel, Denmark, France), with secondary attention to patterns in other regions where data permits.

1.2 Signal Contestation Level

Assessment: HIGH

This phenomenon generates intense interpretive divergence across multiple dimensions:

1. Effectiveness Interpretation: The same vaccine effectiveness data (e.g., 20% VE against Omicron infection, 86% against severe disease) receives radically different interpretations. One grammar reads this as "vaccines work—they prevent severe disease," another as "vaccines failed—they don't stop transmission," and a third as "vaccines serve pharmaceutical profits regardless of marginal effectiveness."

2. Safety Signal Interpretation: VAERS reports of 1.4 million adverse events are read by one grammar as expected background noise in a mass vaccination campaign with robust pharmacovigilance, by another as evidence of widespread harm systematically downplayed, and by a third as a case study in how passive surveillance systems are designed to obscure rather than reveal risk.

3. Policy Intervention Interpretation: Vaccine mandates and certificates that demonstrably increased uptake by 50–100% in the first weeks are read by one grammar as successful public health interventions, by another as coercive violations of bodily autonomy, and by a third as biopolitical control mechanisms that normalized surveillance infrastructure.

4. Trust Dynamics Interpretation: Survey data showing 30% of French respondents lost general vaccine confidence after COVID-19 vaccination campaigns are read by one grammar as a communication failure requiring better messaging, by another as a rational response to broken promises about transmission prevention, and by a third as predictable blowback from coercive policies serving pharmaceutical interests.

1.3 Why This Phenomenon Produces Interpretive Divergence

Structural Factors:

1. Temporal Mismatch Between Evidence and Policy
Vaccine effectiveness data emerged gradually and shifted substantially (high initial efficacy against original strain → waning over months → reduced effectiveness against variants → booster restoration → further waning). Policy interventions (mandates, passports) were often implemented based on earlier effectiveness estimates and maintained even as the evidence base shifted. This temporal lag creates interpretive space: one can emphasize either the initial strong evidence (justifying policies) or the subsequent waning and variant escape (questioning policies), depending on which temporal slice one privileges.

2. Aggregation Paradox
Population-level statistics (vaccines prevent X% of severe disease) and individual-level experiences (person Y had a severe adverse event) operate at different scales and can both be true simultaneously. Grammars differ in which scale they treat as primary. The Institutional-Scientific Grammar privileges population aggregates; the Individual-Autonomy Grammar privileges individual cases; the Critical-Structural Grammar interrogates who benefits from aggregation and whose experiences get statistically erased.

3. Benefit-Risk Asymmetry Across Populations
The benefit-risk calculus for COVID-19 vaccination varies dramatically by age, comorbidity status, prior infection, and variant era. A 75-year-old with diabetes facing Delta has a radically different risk profile than a healthy 25-year-old facing Omicron. Universal policy recommendations (everyone should get vaccinated, everyone should get boosted) paper over this heterogeneity, creating interpretive friction between grammars that privilege population-level herd immunity versus individual-level risk assessment.

4. Institutional Trust as Mediating Variable
The same piece of evidence (e.g., a CDC recommendation) is processed differently depending on one's prior trust in institutions. For those with high institutional trust, official guidance serves as a reliable signal; for those with low trust, the same guidance may be read as propaganda. This creates a hermeneutic spiral: institutions interpret declining trust as a knowledge deficit requiring more messaging, while skeptics interpret more messaging as further evidence of manipulation.

5. Profit Motive Visibility
Pharmaceutical companies earned unprecedented profits from COVID-19 vaccines (Pfizer reported $37 billion in COVID vaccine revenue in 2021 alone, though this figure is not documented in the supplied corpus). This profit motive is either background noise (Institutional-Scientific Grammar: "of course companies profit, but the science is independently validated"), foreground concern (Critical-Structural Grammar: "profit motive shapes research priorities, regulatory relationships, and marketing"), or irrelevant (Individual-Autonomy Grammar: "I don't care about corporate profits; I care about my personal risk").

6. Coercion and Autonomy
Policies that increased uptake (mandates, certificates) did so partly through coercion (loss of employment, exclusion from public spaces). One grammar reads coercion as justified by public health necessity; another reads it as a fundamental violation of bodily autonomy; a third reads it as a case study in how crises are used to normalize authoritarian measures. The empirical fact (policies increased uptake) is uncontested; its meaning is radically contested.

1.4 Major Interpretive Communities

Community 1: Institutional-Scientific
Core Actors: Public health agencies (CDC, WHO, ECDC), academic researchers in epidemiology and infectious disease, major medical journals (NEJM, Lancet, JAMA), mainstream media science desks, professional medical associations.
Characteristic Stance: Vaccines are a major public health success that prevented millions of deaths; waning effectiveness and variant escape are expected evolutionary dynamics requiring updated formulations and boosters; adverse events are rare and vastly outweighed by benefits at the population level; mandates and certificates were justified by the severity of the pandemic and the need to achieve high coverage; declining trust is a communication challenge requiring better public engagement.
Epistemic Authority: Peer-reviewed research, regulatory approval processes, expert consensus, quantitative modeling.

Community 2: Individual-Autonomy / Medical Freedom
Core Actors: Vaccine-hesitant individuals, medical freedom advocacy groups, some libertarian and conservative commentators, alternative health practitioners, segments of social media communities

(particularly on platforms with lighter content moderation).
Characteristic Stance: Individuals have the right to make their own medical decisions without coercion; vaccine effectiveness was oversold (especially regarding transmission prevention); adverse events are more common and severe than officially acknowledged; mandates and certificates were unjustified violations of bodily autonomy; institutional guidance shifted too frequently and lost credibility; natural immunity was undervalued.
Epistemic Authority: Individual testimonies, personal risk assessment, distrust of institutional capture by pharmaceutical interests, emphasis on informed consent and medical autonomy.

Community 3: Critical-Structural / Political Economy
Core Actors: Critical scholars in science and technology studies, medical anthropology, and political economy; left-wing critics of pharmaceutical capitalism; global health equity advocates; some investigative journalists.
Characteristic Stance: The COVID-19 vaccination campaign exemplifies how pharmaceutical capitalism shapes public health priorities (profit over global equity, expensive vaccines over cheap treatments, IP protection over technology transfer); regulatory agencies are captured by industry; mandates served to normalize biopolitical control; the focus on individual vaccination obscured structural determinants of health (poverty, housing, workplace safety); vaccine nationalism and IP hoarding led to preventable deaths in the Global South.
Epistemic Authority: Structural analysis, follow-the-money investigations, attention to power relations, historical patterns of medical colonialism and pharmaceutical malfeasance, solidarity with marginalized communities.

Community 4: Pragmatic-Ambivalent Middle
Core Actors: Large segments of the general public who got vaccinated but harbor doubts, healthcare workers who saw both benefits and harms, journalists trying to report "both sides," policymakers navigating political pressures.
Characteristic Stance: Vaccines probably helped more than they hurt, but the messaging was often overconfident and the coercion felt wrong; some mandates made sense (healthcare workers) while others seemed excessive (young children, people with prior infection); it's hard to know what to believe when experts keep changing their minds; both "trust the science" and "do your own research" feel inadequate.
Epistemic Authority: Eclectic—mixture of institutional guidance, personal experience, peer networks, and case-by-case judgment.

1.5 Why These Communities Cannot Converge

These interpretive communities are not separated by information deficits that more data could resolve. They operate with different:

- Ontological commitments (What is the fundamental nature of the phenomenon? A virus and an immune response? A political crisis? A profit opportunity?)
- Epistemic hierarchies (What counts as reliable knowledge? RCTs? Lived experience? Structural analysis?)
- Moral priorities (What values are paramount? Population health? Individual autonomy? Distributive justice?)
- Temporal horizons (What time scale matters? Immediate pandemic response? Long-term institutional legitimacy? Historical patterns of exploitation?)

More evidence does not resolve these differences; it gets processed through these different grammars and often deepens the divergence. A new safety signal is simultaneously "proof the system works" (Institutional-Scientific), "proof of hidden harms" (Individual-Autonomy), and "proof of inadequate surveillance by design" (Critical-Structural).

Section 2: Signal Set

2.1 Core Signals (Empirical Observations from the 2020–2024 Literature)

Signal 1: High Initial Vaccine Effectiveness Against Severe Disease
Source: Meta-analyses of real-world effectiveness studies across multiple countries and databases [1], [3], [9].
Type: Quantitative clinical outcome data.
Observation: mRNA vaccines (BNT162b2, mRNA-1273) demonstrated 77–84% effectiveness against hospital/emergency department-diagnosed COVID-19 in large matched-cohort studies; effectiveness against severe disease and death remained high (≈90%) even at 5+ months post-vaccination.
Ambiguity Note: "Effectiveness" aggregates across diverse populations, variant eras, and outcome definitions; what counts as "high" depends on comparison point (pre-vaccine mortality vs. initial trial efficacy vs. sterilizing immunity).

Signal 2: Substantial Waning of Protection Against Infection
Source: Longitudinal cohort studies and meta-analyses tracking vaccine effectiveness over time [3], [19], [26], [27].
Type: Quantitative clinical outcome data.
Observation: Vaccine effectiveness against any SARS-CoV-2 infection declined from ~83% at 1 month post-vaccination to ~22% at ≥5 months; waning was more pronounced for infection than for severe disease.
Ambiguity Note: Waning conflates biological immunity decay, behavioral changes (vaccinated individuals may increase risk exposure), and variant evolution; the relative contribution of each is contested.

Signal 3: Markedly Reduced Effectiveness Against Omicron Variant
Source: Systematic reviews and meta-analyses of Omicron-era vaccine effectiveness [6], [7], [10].
Type: Quantitative clinical outcome data.
Observation: Pooled vaccine effectiveness against Omicron infection after primary series was ~20%, declining from ~28% at 3 months to ~4% at 6 months; booster doses restored protection to ~51% against infection and ~86% against severe disease in the short term.
Ambiguity Note: Omicron's reduced severity complicates benefit-risk assessment; preventing infection matters more if infection is severe, less if infection is mild; "failure" vs. "expected viral evolution" depends on framing.

Signal 4: Massive VAERS Reporting Surge in 2021
Source: Longitudinal analysis of VAERS database 1990–2021 [21], [22], [23].
Type: Passive surveillance system data.
Observation: VAERS received 1,396,280 domestic reports over 1990–2021, with 48.52% of all domestic reports occurring in 2021 alone; COVID-19 vaccines (Moderna, Pfizer, Janssen) were the top three vaccines by report count in 2021; most frequently reported symptoms included headache (N=141,186), pyrexia (N=122,120), and fatigue (N=121,910).
Ambiguity Note: VAERS is a passive, uncontrolled reporting system; surge reflects combination of (a) unprecedented vaccination scale, (b) heightened public attention, (c) regulatory encouragement of reporting, and (d) actual adverse events; denominators (doses administered) and causality assessment are not built into raw VAERS counts, making interpretation highly contested.

Signal 5: Vaccine Mandates and Certificates Produced Large Short-Term Uptake Increases
Source: Event-study and difference-in-differences analyses of policy interventions in Canada and Europe [12], [30]; synthetic control studies of certificate policies in six countries [12].
Type: Policy intervention quasi-experimental data.
Observation: Announcement of vaccine mandates associated with >50% increase in first-dose

vaccinations in the first week and >100% in the second week in Canadian provinces; certificate policies in six European countries showed vaccination increases beginning ~20 days before implementation and persisting ~40 days after; estimated net gains included ~289,000 additional first doses in Canada and millions in France, Italy, and Germany.
Ambiguity Note: Increases may include intertemporal substitution (people vaccinating sooner than planned) rather than net new vaccinations; long-term effects on trust and future public health compliance are not captured in short-term uptake metrics.

Signal 6: Substantial Loss of General Vaccine Confidence in Some Populations
Source: Representative surveys in France [8], EU panel studies [11], Danish national surveys [24].
Type: Survey data on trust and confidence.
Observation: In France (April–May 2022), 30% of respondents reported losing general vaccine confidence after the COVID-19 campaign (vs. 13.4% reporting gain); loss was highest among ages 25–34 (45%) and among vaccinated individuals who felt "very constrained" by policies (43.6%); in Denmark, reintroduction of vaccine passports decreased trust in pandemic management by 11 percentage points among unvaccinated individuals.
Ambiguity Note: "Loss of confidence" is self-reported and may reflect (a) actual change in beliefs, (b) social desirability effects, (c) conflation of confidence in COVID vaccines with vaccines generally, or (d) political signaling; causal attribution to specific policies vs. broader pandemic experience is uncertain.

Signal 7: Differential Hesitancy Trends by Race and Ethnicity
Source: Longitudinal state-level analysis in the United States (January–October 2021) [17], individual-level surveys [15].
Type: Survey and administrative data on vaccination intentions and uptake.
Observation: Vaccine hesitancy decreased over time overall, with larger declines among Black populations; vaccine refusal among White populations remained relatively stable; mistrust of vaccine benefit and lower trust in institutions were associated with hesitancy across demographic groups.
Ambiguity Note: Racial disparities in hesitancy are entangled with disparities in healthcare access, historical medical mistreatment (Tuskegee, etc.), and differential exposure to misinformation; whether declining hesitancy among Black populations reflects successful outreach, coercive pressure, or changing risk perception is contested.

Signal 8: AstraZeneca Suspension Increased Hesitancy in Some Subgroups
Source: EU weekly panel study tracking hesitancy before and after March 2021 AstraZeneca suspension [11].
Type: Longitudinal survey data with policy event.
Observation: Temporary suspension of AstraZeneca vaccine in March 2021 due to rare blood clot concerns significantly increased vaccine hesitancy in some subgroups in the EU panel.
Ambiguity Note: Suspension was a regulatory response to a genuine safety signal (thrombosis with thrombocytopenia syndrome); whether the suspension increased hesitancy by revealing risk or by creating perception of institutional uncertainty is contested; counterfactual (not suspending) might have eroded trust differently.

Signal 9: Social Media Discourse Shifted from Uncertainty to Polarization
Source: Thematic analysis of Twitter/X content in Malaysia across 2021 [25].
Type: Qualitative content analysis of social media.
Observation: Social media discourse evolved through three phases: initial uncertainty (early 2021), proactive promotion and correction during rollout (mid-2021), and tension when adolescent vaccination and boosters began (late 2021); more anti-vaccine than pro-vaccine tweets in sample, but community self-correction mechanisms were documented.
Ambiguity Note: Social media content analysis is limited by platform selection, sampling methods, and inability to distinguish bots from humans or to measure reach vs. volume; "polarization" may reflect (a)

genuine opinion shift, (b) algorithmic amplification, or (c) increased willingness to express pre-existing views.

Signal 10: Booster Doses Partially Restored Protection But Waning Continued
Source: Meta-analyses and systematic reviews of booster effectiveness [4], [6], [19].
Type: Quantitative clinical outcome data.
Observation: Booster doses restored vaccine effectiveness against Omicron infection to ~51% within three months (from ~20% after primary series alone) and increased effectiveness against severe disease to ~86%; however, protection against infection waned again over subsequent months.
Ambiguity Note: "Partial restoration" can be framed as success (boosters work) or failure (need for repeated boosting indicates inadequate durability); optimal booster timing and frequency remain contested.

Signal 11: Vaccine Effectiveness Varied Substantially by Brand
Source: Head-to-head comparisons in large claims databases [1], [2].
Type: Quantitative clinical outcome data.
Observation: In matched-cohort studies, mRNA-1273 (Moderna) showed higher effectiveness than BNT162b2 (Pfizer), which in turn outperformed Ad26.COV2.S (Johnson & Johnson); e.g., 84% vs. 77% vs. 66% against hospital/ED-diagnosed COVID-19.
Ambiguity Note: Brand differences may reflect (a) true biological differences (dose, formulation, dosing interval), (b) population differences (who received which vaccine when), or (c) variant era confounding; policy implications (should one brand be preferred?) are contested.

Signal 12: Trust in Science Correlated with Lower Hesitancy; Trust in Social Media Correlated with Higher Hesitancy
Source: EU panel study with multivariable analysis [11].
Type: Survey data with statistical modeling.
Observation: Higher trust in science was associated with lower vaccine hesitancy; trust in social media and using social media as main information source were positively associated with hesitancy.
Ambiguity Note: Correlation does not establish causation; "trust in science" may proxy for education, political orientation, or personality traits; "social media" is heterogeneous (Facebook ≠ Twitter ≠ Telegram); directionality is unclear (does social media use cause hesitancy, or do hesitant people seek out social media?).

Signal 13: Mandates Increased Uptake But Were Associated with Feelings of Coercion and Trust Decline
Source: French survey on constraint and confidence [8], Danish survey on passport reintroduction [24], Canadian and European mandate studies [30].
Type: Survey data and policy quasi-experiments.
Observation: Policies that increased uptake (mandates, certificates) were also associated with self-reported feelings of coercion and, among those who felt constrained, substantial loss of vaccine confidence (43.6% in France) and trust in pandemic management (11-point decline in Denmark among unvaccinated).
Ambiguity Note: Trade-off between short-term uptake gains and long-term trust erosion is contested; whether trust decline is (a) a necessary cost of effective policy, (b) a sign of policy failure, or (c) a predictable response to authoritarianism depends on grammar.

Signal 14: Vaccine Effectiveness Sustained Longer for Severe Outcomes Than for Infection
Source: Longitudinal cohort studies and meta-analyses [1], [3], [19].
Type: Quantitative clinical outcome data.
Observation: Vaccine effectiveness against severe disease (hospitalization, death) remained high (~90%) at 5+ months post-vaccination, while effectiveness against any infection declined to ~22%; effectiveness was sustained for ~7 months for medically-diagnosed COVID-19 and up to 9 months for hospital/ED-diagnosed COVID-19.
Ambiguity Note: Differential waning by outcome severity is consistent with immunological theory (memory

B and T cells provide durable protection against severe disease even as neutralizing antibodies wane), but policy implications are contested: does this mean vaccines "work" (they prevent death) or "fail" (they don't prevent infection and transmission)?

Signal 15: Modeling Studies Estimated Millions of Deaths Averted by Vaccination
Source: Global and regional modeling studies [28], [29].
Type: Counterfactual modeling.
Observation: Mathematical models estimated that COVID-19 vaccination averted millions of deaths globally in the first year of rollout (2021) and hundreds of thousands of deaths among elderly populations in the WHO European Region (December 2020 to November 2021).
Ambiguity Note: Modeling estimates depend on assumptions about counterfactual scenarios (what would have happened without vaccines?), infection fatality rates, and transmission dynamics; models are not direct observations but inference engines; different modeling choices yield different estimates.

2.2 Counter-Signals (Observations That Complicate or Challenge Dominant Narratives)

Counter-Signal 1: Vaccine Effectiveness Against Infection Approached Zero for Some Variant-Time Combinations
Source: Meta-analyses of Omicron effectiveness [6].
Type: Quantitative clinical outcome data.
Observation: Pooled vaccine effectiveness against Omicron infection declined to ~4% at 6 months post-primary series (before booster).
Challenge: This contradicts early messaging that vaccines would provide robust, durable protection against infection; it supports the Individual-Autonomy Grammar's claim that vaccine effectiveness was oversold and the Critical-Structural Grammar's claim that vaccines were marketed beyond their actual performance.

Counter-Signal 2: Unprecedented Scale of Adverse Event Reporting
Source: VAERS longitudinal analysis [21].
Type: Passive surveillance data.
Observation: Nearly half of all VAERS reports from 1990–2021 occurred in 2021 alone; COVID-19 vaccines generated more reports in one year than all other vaccines combined over the previous three decades.
Challenge: While the Institutional-Scientific Grammar attributes this to scale and heightened attention, the Individual-Autonomy Grammar reads it as evidence of unusual harm, and the Critical-Structural Grammar reads it as revealing the inadequacy of passive surveillance systems that were never designed to detect rare but serious harms at population scale.

Counter-Signal 3: Policies That Increased Uptake Also Eroded Trust
Source: French and Danish surveys [8], [24].
Type: Survey data.
Observation: Mandates and certificates achieved their proximate goal (increased vaccination) but were associated with substantial trust decline, particularly among those who felt coerced.
Challenge: This complicates the Institutional-Scientific Grammar's framing of mandates as unambiguous public health successes; it supports the Individual-Autonomy Grammar's emphasis on autonomy violations and the Critical-Structural Grammar's concern about normalization of coercive biopolitical measures.

Counter-Signal 4: Younger Populations Lost More Vaccine Confidence Than Older Populations
Source: French survey [8].
Type: Survey data.
Observation: Loss of general vaccine confidence after COVID-19 campaign was highest among ages 25–34 (45%) vs. >75 (14.6%).
Challenge: This is the opposite of what a simple benefit-risk model would predict (older populations

benefited more from COVID vaccines and should have gained more confidence); it suggests that confidence loss is driven by factors other than personal benefit (e.g., perceived coercion, broken promises about transmission, generational differences in institutional trust).

Counter-Signal 5: Natural Immunity Underrepresented in Policy and Research
Source: Implicit in the literature's focus on vaccine-induced immunity; noted in some studies as a limitation [1].
Type: Absence of evidence (gap in research focus).
Observation: The supplied corpus contains extensive data on vaccine effectiveness but minimal comparative data on natural immunity (post-infection protection) or hybrid immunity (infection + vaccination); policy interventions (mandates, certificates) rarely exempted those with prior infection.
Challenge: This gap supports the Individual-Autonomy Grammar's claim that policy was driven by vaccination targets rather than immunity targets, and the Critical-Structural Grammar's claim that pharmaceutical interests shaped research and policy priorities.

2.3 Contested Signals (Observations Interpreted Radically Differently by Different Grammars)

Contested Signal 1: The Meaning of "Vaccine Effectiveness"

What the Signal IS According to Each Grammar:

- Institutional-Scientific Grammar: Vaccine effectiveness is a population-level statistical measure comparing outcomes (infection, hospitalization, death) between vaccinated and unvaccinated groups, adjusted for confounders; it is the gold standard for assessing real-world vaccine performance and guiding policy; VE of 77–84% against hospitalization means vaccines are highly effective.

- Individual-Autonomy Grammar: Vaccine effectiveness is a probabilistic estimate that may or may not apply to my individual case; it conflates diverse populations and risk profiles; "effectiveness" against hospitalization is irrelevant if my baseline risk of hospitalization is near-zero (young, healthy, no comorbidities); what matters is my personal benefit-risk calculation, not population averages.

- Critical-Structural Grammar: Vaccine effectiveness is a metric that serves pharmaceutical and public health interests by focusing attention on individual-level biological intervention rather than structural determinants of health (poverty, housing, workplace safety); it is produced by research funded by vaccine manufacturers and regulators with revolving-door relationships to industry; the metric itself is not neutral but reflects power relations in knowledge production.

Contested Signal 2: The Meaning of VAERS Reports

What the Signal IS According to Each Grammar:

- Institutional-Scientific Grammar: VAERS is a passive surveillance system designed for hypothesis generation, not causal inference; the surge in reports reflects unprecedented vaccination scale, heightened public attention, and regulatory encouragement of reporting; the system is working as intended by detecting rare signals (e.g., myocarditis) for further investigation; raw report counts without denominators and causality assessment are meaningless.

- Individual-Autonomy Grammar: VAERS reports represent real people experiencing real harms; the surge in reports is a signal that these vaccines are causing more adverse events than previous vaccines; the fact that reports are dismissed as "not proven causal" reflects institutional bias toward

minimizing harm; individuals have a right to know about these reports when making their own risk assessments.

- Critical-Structural Grammar: VAERS is a passive system designed to obscure rather than reveal harm; it places the burden of reporting on individuals and healthcare providers who face disincentives to report (time, dismissal of concerns, fear of being labeled "anti-vaccine"); the system's limitations are not accidental but reflect regulatory capture and the prioritization of vaccine uptake over safety surveillance; the surge in reports is a signal of both actual harm and system inadequacy.

Contested Signal 3: The Meaning of Vaccine Mandates

What the Signal IS According to Each Grammar:

- Institutional-Scientific Grammar: Mandates are evidence-based public health interventions justified by the severity of the pandemic, the effectiveness of vaccines, and the need to achieve high coverage for population protection; they are analogous to other vaccine mandates (measles, polio) that have been successful and widely accepted; the empirical fact that mandates increased uptake by 50–100% demonstrates their effectiveness.

- Individual-Autonomy Grammar: Mandates are coercive violations of bodily autonomy and informed consent; they force individuals to accept a medical intervention with uncertain long-term safety and waning effectiveness; the fact that mandates "worked" to increase uptake is irrelevant—effectiveness does not justify coercion; mandates set a dangerous precedent for government control over medical decisions.

- Critical-Structural Grammar: Mandates are biopolitical control mechanisms that normalize state and corporate power over bodies; they disproportionately impact working-class people who cannot afford to lose their jobs; they serve pharmaceutical profits by guaranteeing a captive market; they are part of a broader pattern of using crises to expand authoritarian measures that persist after the crisis ends; the focus on individual vaccination obscures structural failures (inadequate sick leave, unsafe workplaces, lack of universal healthcare).

Contested Signal 4: The Meaning of Waning Effectiveness

What the Signal IS According to Each Grammar:

- Institutional-Scientific Grammar: Waning effectiveness is an expected immunological phenomenon (antibody titers decline over time) and an expected evolutionary phenomenon (viruses evolve to escape immunity); it is not a "failure" but a normal dynamic that requires updated vaccines and booster doses, just as influenza vaccines are updated annually; the fact that boosters restore protection demonstrates that the vaccine platform works.

- Individual-Autonomy Grammar: Waning effectiveness is evidence that initial promises about vaccine durability were false; I was told vaccines would provide long-lasting protection, but now I'm being told I need boosters every few months indefinitely; this moving goalpost erodes trust and suggests that institutions either didn't know what they were claiming or deliberately oversold the product; I have a right to decline repeated boosting.

- Critical-Structural Grammar: Waning effectiveness is a feature, not a bug, from the perspective of pharmaceutical capitalism; vaccines that require repeated boosting generate recurring revenue streams; the focus on boosting individuals rather than addressing structural factors (global vaccine

equity, technology transfer, development of variant-proof vaccines) reflects profit priorities; waning effectiveness also serves to justify ongoing emergency measures and surveillance infrastructure.

Section 3: Grammar Specifications

3.1 Grammar 1: Institutional-Scientific Grammar

Source Traditions: Evidence-based medicine, public health epidemiology, regulatory science, peer-review culture, Enlightenment rationalism, technocratic governance.

Grammar Boundary Specifications: This grammar operates within the boundaries of institutionally validated knowledge production. It accepts as legitimate only claims that have passed through formal validation mechanisms (peer review, regulatory approval, expert consensus). It excludes from consideration claims based solely on individual testimony, structural critique without quantitative evidence, or challenges to the legitimacy of scientific institutions themselves. The boundary is policed by credentialing (who is qualified to speak?), methodology (what counts as rigorous evidence?), and publication venue (where did this appear?).

Nine Parameters:

1) Primary Analytical Variable
Population-level health outcomes (infection rates, hospitalization rates, mortality rates, vaccine effectiveness percentages, adverse event incidence rates). The fundamental question is: "What is the aggregate effect on measurable health outcomes?"

2) Signal Selection Rules
Prioritize signals from:

- Peer-reviewed publications in high-impact journals
- Large-scale observational studies with robust statistical adjustment
- Randomized controlled trials (gold standard)
- Official surveillance systems (VAERS, V-safe, Yellow Card)
- Regulatory agency reports (FDA, EMA, CDC)
- Meta-analyses and systematic reviews

Exclude or downweight:

- Individual anecdotes without systematic collection
- Non-peer-reviewed sources (social media, blogs, preprints without subsequent publication)
- Studies with small sample sizes or weak methodology
- Claims that contradict expert consensus without extraordinary evidence

3) Weighting Priority
Weight signals by:

- Study design hierarchy (RCT > cohort > case-control > case series > anecdote)
- Sample size (larger N = more weight)
- Statistical precision (narrower confidence intervals = more weight)
- Replication (findings replicated across multiple studies = more weight)
- Institutional prestige (top journals, leading universities = more weight)

4) Causal Chain Type
Biological-mechanistic causation validated by statistical association. The causal chain runs: virus → immune response → clinical outcome, mediated by vaccine-induced immunity. Causation is established through:

- Biological plausibility (does the mechanism make sense?)
- Temporal sequence (did vaccination precede outcome?)
- Dose-response relationship (more vaccine = more protection?)
- Statistical association (are outcomes different between vaccinated and unvaccinated?)
- Consistency across studies (do multiple studies find the same effect?)

5) Admissible Closure
"Vaccines are safe and effective." Specifically:

- mRNA COVID-19 vaccines provide strong protection against severe disease and death
- Protection against infection wanes over time and is reduced against variants, but boosters restore protection
- Serious adverse events are rare and vastly outweighed by benefits at the population level
- Vaccine mandates and certificates were justified public health interventions that increased uptake and saved lives
- Declining trust is a communication challenge requiring better public engagement and combating of misinformation

6) Excluded Signals

- Individual adverse event testimonies that have not been validated through formal causality assessment
- Structural critiques of pharmaceutical industry influence that lack quantitative evidence of bias in specific studies
- Claims about "natural immunity" superiority that are not based on head-to-head comparative studies
- Concerns about long-term safety that are speculative (no mechanism, no evidence)
- Framing of mandates as "coercion" rather than "public health necessity"

7) Characteristic Vocabulary
Vaccine effectiveness, confidence intervals, statistical significance, peer-reviewed, evidence-based, risk-benefit ratio, herd immunity, pharmacovigilance, adverse event incidence, population health, public health intervention, misinformation, vaccine hesitancy, health communication.

8) Temporal Orientation
Present-focused with near-future projection. Privileges the most recent data (current variant, latest VE estimates, newest safety signals) and uses this to make near-term recommendations (should people get boosted now? which populations should be prioritized?). Historical context is invoked selectively (history of vaccine development, past pandemics) but primarily to support present claims. Long-term historical patterns (decades of pharmaceutical industry behavior, erosion of public trust) are backgrounded.

9) Temporal Formation
Cumulative and progressive. Knowledge builds over time as more studies are published, more data accumulate, and consensus emerges. Early uncertainty (2020: "we don't know how long immunity lasts") gives way to later clarity (2022: "we now know immunity wanes and boosters are needed"). Errors are corrected through the self-correcting mechanism of science. The temporal arc is toward increasing knowledge and better interventions.

3.2 Grammar 2: Individual-Autonomy Grammar

Source Traditions: Medical ethics (informed consent, bodily autonomy), libertarian political philosophy, patient rights movements, medical freedom advocacy, consumer protection, distrust of institutional authority.

Grammar Boundary Specifications: This grammar operates within the boundaries of individual rights and personal sovereignty. It accepts as legitimate any claim that bears on an individual's right to make their own medical decisions free from coercion. It excludes from consideration arguments based solely on population-level benefits that override individual autonomy, appeals to collective responsibility that subordinate individual rights, or institutional authority claims that bypass informed consent. The boundary is policed by the principle of bodily autonomy: no one may be forced to accept a medical intervention regardless of population-level benefits.

Nine Parameters:

1) Primary Analytical Variable
Individual benefit-risk assessment and autonomy preservation. The fundamental question is: "What is the benefit and risk to me personally, and am I free to make my own choice?"

2) Signal Selection Rules
Prioritize signals from:

- Individual testimonies and case reports (especially adverse events)
- Studies that stratify risk by age, comorbidity, and prior infection (not just population averages)
- Data on adverse events, even if rare or not definitively causal
- Evidence of institutional overreach (mandates, coercion, censorship)
- Information about alternative treatments and natural immunity
- Sources that challenge official narratives (dissenting experts, investigative journalism)

Exclude or downweight:

- Population-level statistics that obscure individual variation
- Appeals to collective responsibility that override individual rights
- Institutional pronouncements that lack transparency about uncertainty and limitations
- Studies funded by vaccine manufacturers (conflict of interest)

3) Weighting Priority
Weight signals by:

- Relevance to personal risk profile (my age, my health status, my prior infection)
- Severity of potential harm (death and disability weighted more than mild illness)
- Certainty of information (known risks weighted more than uncertain benefits)
- Transparency and honesty (sources that acknowledge uncertainty weighted more than those that oversell)
- Independence from institutional and financial conflicts of interest

4) Causal Chain Type
Individual-level probabilistic causation with emphasis on personal agency. The causal chain runs: my decision → my outcome, mediated by my unique risk factors and values. Causation is assessed through:

- Personal risk calculation (what is my baseline risk? what is my vaccine risk?)
- Precautionary principle (when in doubt, preserve autonomy and avoid irreversible interventions)

- Temporal proximity (if I got vaccinated and then had an adverse event, the vaccine is a plausible cause regardless of statistical proof)
- Lived experience (my body, my experience, my judgment)

5) Admissible Closure
"Individuals have the right to make their own medical decisions based on their own risk assessment." Specifically:

- COVID-19 vaccines may benefit some people (elderly, high-risk) but not others (young, healthy, prior infection)
- Vaccine effectiveness was oversold, especially regarding transmission prevention and durability
- Adverse events are more common and more serious than officially acknowledged
- Mandates and certificates were unjustified violations of bodily autonomy and informed consent
- Natural immunity provides substantial protection and should be recognized in policy
- Individuals should be free to weigh their own risks and benefits without coercion

6) Excluded Signals

- Population-level benefits that are used to justify coercion of individuals
- Statistical dismissals of individual adverse event experiences ("not proven causal")
- Appeals to herd immunity that subordinate individual rights to collective goals
- Institutional authority claims that bypass individual informed consent
- Framing of vaccine refusal as "misinformation" or "hesitancy" rather than legitimate choice

7) Characteristic Vocabulary
Bodily autonomy, informed consent, medical freedom, personal choice, individual rights, coercion, mandate, natural immunity, adverse events, risk-benefit assessment, medical ethics, patient sovereignty, censorship, institutional overreach.

8) Temporal Orientation
Present-focused with emphasis on immediate decision urgency. The temporal frame is: "I must decide now whether to get vaccinated (or boosted), and I must live with the consequences of that decision for the rest of my life." Future orientation is toward personal long-term safety (will I regret this decision in 10 years?). Historical context is invoked selectively (past medical scandals like Tuskegee, thalidomide, opioid crisis) to justify present distrust.

9) Temporal Formation
Episodic and experiential. Knowledge is formed through personal experience and the experiences of trusted others. Official guidance that changes over time (masks don't work → masks work; vaccines prevent transmission → vaccines don't prevent transmission; two doses are enough → you need boosters) is read not as science updating itself but as evidence of institutional incompetence or dishonesty. The temporal arc is toward increasing distrust as promises are broken and goalposts move.

3.3 Grammar 3: Critical-Structural Grammar

Source Traditions: Political economy, critical theory, science and technology studies, medical anthropology, postcolonial studies, history of medicine, investigative journalism, social movements for health justice.

Grammar Boundary Specifications: This grammar operates within the boundaries of structural power analysis. It accepts as legitimate any claim that illuminates how power, profit, and inequality shape health outcomes and knowledge production. It excludes from consideration analyses that treat scientific knowledge as politically neutral, that ignore the role of capital in shaping research and policy, or that frame

health as primarily an individual biological phenomenon rather than a social and political one. The boundary is policed by the question: "Cui bono?" (Who benefits?)

Nine Parameters:

1) Primary Analytical Variable
Power relations, profit flows, and structural inequality. The fundamental question is: "Who benefits from this arrangement, and whose interests are served by this framing?"

2) Signal Selection Rules
Prioritize signals from:

- Follow-the-money investigations (pharmaceutical revenues, lobbying expenditures, revolving doors)
- Studies documenting health inequities by race, class, geography
- Historical patterns of medical exploitation and pharmaceutical malfeasance
- Regulatory capture and conflicts of interest
- Global vaccine inequity (vaccine nationalism, IP hoarding, technology transfer refusal)
- Voices of marginalized communities and critical scholars
- Evidence of censorship, deplatforming, and suppression of dissent

Exclude or downweight:

- Analyses that treat scientific institutions as neutral arbiters
- Studies that ignore funding sources and conflicts of interest
- Framings that individualize structural problems (vaccine hesitancy as knowledge deficit rather than rational distrust)
- Population health metrics that obscure distributional inequities

3) Weighting Priority
Weight signals by:

- Structural significance (does this reveal systemic patterns or just individual cases?)
- Power asymmetry (does this illuminate how the powerful exploit the vulnerable?)
- Historical resonance (does this fit patterns of past exploitation?)
- Distributional impact (who bears the costs? who reaps the benefits?)
- Resistance to institutional narratives (does this challenge official stories?)

4) Causal Chain Type
Structural-political causation operating through institutions, markets, and power relations. The causal chain runs: capitalist imperatives (profit maximization) → institutional arrangements (regulatory capture, IP protection, research priorities) → knowledge production (what gets studied, what gets published) → policy (mandates, global inequity) → outcomes (who lives, who dies, who profits). Causation is assessed through:

- Cui bono analysis (who benefits financially and politically?)
- Historical pattern recognition (does this repeat past exploitation?)
- Structural logic (what do capitalist/state imperatives predict?)
- Power mapping (who has power to set agendas and define problems?)

5) Admissible Closure
"The COVID-19 vaccination campaign exemplifies pharmaceutical capitalism and biopolitical control." Specifically:

- Vaccines were developed and distributed according to profit logic, not global health need (vaccine nationalism, IP hoarding, price gouging)
- Regulatory agencies are captured by industry through funding, revolving doors, and shared interests

- Research priorities were shaped by pharmaceutical interests (focus on expensive vaccines over cheap treatments, on individual intervention over structural change)
- Mandates served to normalize biopolitical control and surveillance infrastructure
- The focus on individual vaccination obscured structural determinants of health (poverty, racism, unsafe workplaces)
- Dissent was suppressed through deplatforming, professional sanctions, and accusations of "misinformation"
- The pandemic was a windfall for pharmaceutical companies and a disaster for global health equity

6) Excluded Signals

- Claims that scientific institutions are neutral and apolitical
- Analyses that ignore pharmaceutical profit motives and regulatory capture
- Framings that treat vaccine mandates as purely public health interventions rather than exercises of state power
- Population health metrics that obscure how benefits and harms are distributed by race, class, and geography
- Dismissals of "conspiracy theories" that foreclose investigation of actual conspiracies (price-fixing, lobbying, suppression of generic competition)

7) Characteristic Vocabulary
Pharmaceutical capitalism, regulatory capture, biopolitical control, structural determinants of health, health inequity, vaccine nationalism, intellectual property, technology transfer, profit motive, revolving door, conflict of interest, medical colonialism, surveillance infrastructure, coercion, resistance, solidarity.

8) Temporal Orientation
Long historical horizon with attention to structural continuity. The temporal frame extends decades or centuries: the COVID-19 vaccination campaign is situated within the history of pharmaceutical capitalism (opioid crisis, HIV/AIDS treatment access, etc.), medical colonialism (Tuskegee, forced sterilization, etc.), and the neoliberal erosion of public health infrastructure. Present events are read as instantiations of long-term structural patterns. Future orientation is toward structural transformation (socialized pharmaceutical R&D, global health equity, dismantling of IP regimes).

9) Temporal Formation
Cyclical and structural. History repeats itself because underlying power structures persist. The pharmaceutical industry's behavior during COVID-19 (profit maximization, IP hoarding, regulatory capture) replicates its behavior during past crises (HIV/AIDS, H1N1, etc.). Official narratives change (early: "vaccines prevent transmission" → later: "vaccines prevent severe disease"), but structural arrangements persist (profit motive, regulatory capture, global inequity). The temporal arc is not toward progress but toward the reproduction of inequality unless structural transformation occurs.

Section 4: Signal Processing

4.1 Processing Through Institutional-Scientific Grammar

The COVID-19 vaccination campaign represents one of the most remarkable achievements in the history of public health and biomedical science. Within one year of the pandemic's onset, multiple highly effective vaccines were developed, tested in large-scale randomized controlled trials, and deployed globally. The empirical evidence from real-world effectiveness studies demonstrates that these vaccines have saved millions of lives.

Vaccine Effectiveness: Strong Protection Against Severe Disease

The core signal is unambiguous: mRNA vaccines (BNT162b2 and mRNA-1273) provide strong, durable protection against severe COVID-19 outcomes. Meta-analyses of large matched-cohort studies across multiple countries and databases show vaccine effectiveness of 77–84% against hospital and emergency department-diagnosed COVID-19 [1]. More importantly, protection against severe disease and death remained high—approximately 90%—even at five or more months post-vaccination [3]. This sustained protection against the outcomes that matter most (hospitalization and death) is the fundamental success of these vaccines.

The differential waning pattern—faster decline in protection against infection than against severe disease—is consistent with established immunological principles. Neutralizing antibodies, which prevent infection, decline over time, while memory B cells and T cells, which prevent severe disease, remain more durable [19]. This is not a failure of the vaccines but a reflection of how adaptive immunity works. The fact that protection against death and severe disease remains robust even as protection against mild infection wanes means the vaccines are doing exactly what they were designed to do: prevent the healthcare system from being overwhelmed and prevent mass mortality.

Variant Evolution and Booster Response

The emergence of the Omicron variant in late 2021 presented a significant immune escape challenge. Pooled vaccine effectiveness against Omicron infection after the primary series was approximately 20%, declining to near-zero at six months [6]. However, this must be contextualized: Omicron was also intrinsically less severe than earlier variants, and booster doses substantially restored protection. After a booster, vaccine effectiveness against Omicron infection increased to approximately 51%, and effectiveness against severe Omicron disease reached 86% [4].

This pattern demonstrates both the challenge of viral evolution and the adaptability of the vaccine platform. The fact that boosters restore protection—even against a variant with substantial immune escape—shows that the mRNA platform is working as intended. The need for boosters is not a failure; it is analogous to annual influenza vaccination, where vaccines are updated to match circulating strains. The difference is that SARS-CoV-2 evolved faster than anticipated, requiring more frequent boosting than initially hoped.

Brand Comparisons and Optimization

Head-to-head comparisons in large claims databases reveal meaningful differences in vaccine effectiveness by brand. mRNA-1273 (Moderna) consistently outperformed BNT162b2 (Pfizer), which in turn outperformed Ad26.COV2.S (Johnson & Johnson): 84% vs. 77% vs. 66% against hospital/ED-diagnosed COVID-19 [1]. These differences likely reflect biological factors—mRNA-1273 uses a higher dose and a longer interval between doses—rather than population confounding, given the robust matching and adjustment in these studies.

From a public health perspective, these findings suggest that mRNA vaccines should be preferred over adenovirus-vector vaccines, and that within mRNA vaccines, mRNA-1273 may offer marginally better protection. However, all three vaccines provide substantial protection against severe disease, and the best vaccine is the one that is available and that people are willing to take. The perfect should not be the enemy of the good.

Safety Surveillance: Robust Pharmacovigilance

The surge in VAERS reports in 2021—with nearly half of all reports from 1990–2021 occurring in that single year—reflects the unprecedented scale of the vaccination campaign and heightened public and regulatory attention, not an unprecedented safety crisis [21]. In 2021 alone, over 600 million COVID-19 vaccine doses

were administered in the United States. The most frequently reported symptoms—headache, pyrexia (fever), and fatigue—are expected reactogenic responses to vaccination, not serious adverse events [22].

VAERS is a passive surveillance system designed for hypothesis generation, not for establishing causation or calculating incidence rates. The system lacks denominators (how many people were vaccinated?) and does not adjudicate causality (did the vaccine cause this event, or did it occur coincidentally after vaccination?). The fact that VAERS detected rare but serious signals—such as myocarditis after mRNA vaccination in young males and thrombosis with thrombocytopenia syndrome after adenovirus-vector vaccination—demonstrates that the system is working as intended. These signals were rapidly investigated, quantified, and incorporated into risk-benefit assessments and clinical guidance.

The risk-benefit calculus remains overwhelmingly favorable. Myocarditis after mRNA vaccination is rare (approximately 12 cases per million second doses in young males), typically mild, and resolves without long-term sequelae. In contrast, COVID-19 infection itself carries a much higher risk of myocarditis, as well as risks of hospitalization, long COVID, and death. At the population level, the benefits of vaccination vastly outweigh the risks across all age groups, though the margin is narrower for young, healthy individuals facing Omicron than for elderly individuals facing Delta.

Policy Interventions: Effective Public Health Measures

Vaccine mandates and certificate policies achieved their intended goal: increasing vaccine uptake. Event-study and difference-in-differences analyses demonstrate that mandate announcements were associated with large increases in first-dose vaccinations—more than 50% in the first week and more than 100% in the second week in Canadian provinces [30]. Synthetic control studies of certificate policies in six European countries found similar patterns, with vaccination increases beginning approximately 20 days before implementation and persisting for 40 days after [12].

These policies were justified by the severity of the pandemic, the effectiveness of vaccines in preventing severe disease and death, and the need to achieve high population coverage to reduce transmission and protect vulnerable individuals. The ethical framework is straightforward: individual autonomy is not absolute when individual choices impose externalities on others. Just as we require seatbelts, prohibit drunk driving, and mandate childhood vaccinations for school entry, we can require COVID-19 vaccination in settings where unvaccinated individuals pose risks to others (healthcare facilities, congregate settings, public venues during a pandemic).

The fact that some individuals felt coerced is regrettable but does not invalidate the policy. Public health often involves trade-offs between individual preferences and collective welfare. The alternative—allowing the pandemic to continue unchecked, overwhelming healthcare systems, and causing preventable deaths—was ethically unacceptable.

Addressing Counter-Signals

Several counter-signals require acknowledgment and contextualization:

Waning effectiveness against infection: This is an expected immunological and evolutionary phenomenon, not a failure. The vaccines were designed and tested primarily for their ability to prevent severe disease and death, which they continue to do effectively. The early hope that they would also provide sterilizing immunity and halt transmission was based on preliminary data and was revised as more evidence accumulated. This is how science works: updating beliefs in light of new evidence.

Trust decline in some populations: Survey data showing loss of vaccine confidence, particularly among younger adults and those who felt constrained by policies, is concerning and requires attention [8], [24]. However, this likely reflects a combination of factors: unrealistic initial expectations (vaccines would end the pandemic immediately), frustration with changing guidance (masks, boosters), and political polarization.

The solution is better health communication that is transparent about uncertainty, acknowledges trade-offs, and rebuilds trust through consistent, honest messaging.

Unprecedented VAERS reporting: As noted above, this reflects scale and attention, not unprecedented harm. The pharmacovigilance system detected rare serious adverse events (myocarditis, TTS) and incorporated them into risk-benefit assessments. The system worked.

Younger populations losing confidence: This is puzzling from a benefit-risk perspective, since older populations benefited more from vaccination. It likely reflects generational differences in institutional trust, greater exposure to social media misinformation, and the fact that younger individuals faced lower baseline COVID-19 risk and thus had less personal experience of vaccine benefit. This is a communication and trust challenge, not an indictment of the vaccines themselves.

Closure Statement

The evidence is clear: COVID-19 vaccines are safe and effective. They provide strong, durable protection against severe disease and death. Protection against infection wanes over time and is reduced against variants, but booster doses restore protection. Serious adverse events are rare and vastly outweighed by benefits at the population level. Vaccine mandates and certificates were justified public health interventions that increased uptake and saved lives. Declining trust in some populations is a communication challenge that requires transparent, honest engagement and combating of misinformation.

The COVID-19 vaccination campaign prevented millions of deaths globally and represents a triumph of biomedical science, regulatory agility, and public health infrastructure. Challenges remain—ensuring global vaccine equity, updating vaccines to match circulating variants, rebuilding trust—but the fundamental success of the vaccines is beyond dispute.

Note on Closure: This closure is the product of processing the signal set through the Institutional-Scientific Grammar's rules (prioritizing peer-reviewed quantitative evidence, weighting by study design and sample size, framing causation in biological-mechanistic terms, excluding signals that lack institutional validation). It is not a verdict on reality itself, but rather the conclusion that this grammar's architecture produces when applied to this signal set.

4.2 Processing Through Individual-Autonomy Grammar

The COVID-19 vaccination campaign has been characterized by institutional overreach, broken promises, and systematic dismissal of individual rights and experiences. While vaccines may benefit some high-risk individuals, the one-size-fits-all approach—backed by coercive mandates and certificates—violated fundamental principles of medical ethics and bodily autonomy.

Oversold Effectiveness and Moving Goalposts

The initial promise was clear: get vaccinated and return to normal life. Vaccines were presented as highly effective at preventing infection and transmission. President Biden stated in July 2021, "You're not going to get COVID if you have these vaccinations." CDC Director Walensky said vaccinated people "don't carry the virus." These were not nuanced scientific statements acknowledging uncertainty; they were categorical promises.

Those promises were false. Real-world data show that vaccine effectiveness against infection waned rapidly—from 83% at one month to 22% at five months [3]—and approached zero against Omicron at six months post-primary series [6]. Vaccines did not prevent infection or transmission as promised. The

goalposts moved: first it was "get vaccinated to protect yourself and others," then it was "get vaccinated to reduce your risk of severe disease," then it was "get boosted," then it was "get boosted again."

This moving target erodes trust. If institutions were wrong about transmission prevention and durability, what else are they wrong about? If they oversold the product initially—whether through ignorance or deliberate deception—why should I trust their current claims about safety and the need for repeated boosting?

Individual Risk Stratification Ignored

The benefit-risk calculus for COVID-19 vaccination varies dramatically by age, health status, and prior infection. An elderly person with diabetes facing Delta has a very different risk profile than a healthy 25-year-old with prior infection facing Omicron. Yet policy treated everyone the same: everyone should get vaccinated, everyone should get boosted, regardless of individual circumstances.

For young, healthy individuals with low baseline risk of severe COVID-19, the absolute benefit of vaccination is small. If my risk of hospitalization from COVID-19 is near-zero, then even a highly effective vaccine provides minimal absolute benefit to me. Meanwhile, I bear the full risk of adverse events, however rare. This is my calculation to make, not the government's or my employer's.

Natural immunity—protection from prior infection—was systematically ignored in policy. Mandates and certificates rarely exempted those with prior infection, despite evidence that natural immunity provides substantial protection. This reveals that policy was driven by vaccination targets, not immunity targets. The goal was to get needles in arms, not to achieve population immunity through the most appropriate means for each individual.

Adverse Events: Dismissed and Downplayed

The surge in VAERS reports in 2021—nearly half of all reports from 1990–2021 occurring in that single year—is a signal that cannot be dismissed as merely "scale and attention" [21]. These are real people experiencing real harms: headaches, fevers, fatigue, and in some cases more serious events like myocarditis, blood clots, and neurological problems.

The institutional response to adverse event reports is to immediately emphasize that "correlation does not equal causation" and that VAERS reports are "not verified." This is technically true but functionally dismissive. When someone gets vaccinated and then experiences a serious health problem, the temporal proximity makes the vaccine a plausible cause. The burden should be on the vaccine to prove it didn't cause the harm, not on the injured person to prove it did.

Moreover, VAERS is a passive system that likely captures only a fraction of actual adverse events. Healthcare providers are busy, reporting is time-consuming, and there are social and professional disincentives to reporting (fear of being labeled "anti-vaccine," dismissal of concerns by colleagues). If VAERS shows 1.4 million reports, the true number of adverse events is likely much higher.

Individuals have a right to know about these reports when making their own risk assessments. The fact that institutions dismiss them as "not proven causal" reflects a bias toward minimizing harm and maximizing uptake, not a neutral assessment of evidence.

Coercion and Autonomy Violations

Vaccine mandates and certificates were coercive violations of bodily autonomy and informed consent. People were told: get vaccinated or lose your job, get vaccinated or be excluded from restaurants and gyms, get vaccinated or be barred from travel. This is not a free choice; it is coercion.

The empirical fact that mandates increased uptake by 50–100% [30] does not justify them. Effectiveness is not the same as ethics. A policy can "work" in the narrow sense of achieving its proximate goal (more vaccinations) while being fundamentally wrong. Forcing people to accept a medical intervention with uncertain long-term safety and waning effectiveness is a violation of the Nuremberg Code's principle of voluntary informed consent.

The long-term consequences of these policies are profound. Survey data show that mandates and certificates were associated with substantial loss of vaccine confidence—43.6% among those who felt "very constrained" in France [8]—and trust decline in pandemic management [24]. People who were coerced into vaccination are less likely to trust public health institutions in the future. The short-term gain in uptake came at the cost of long-term trust erosion.

Moreover, mandates set a dangerous precedent. If the government can force you to accept a COVID-19 vaccine, what else can it force you to accept? Where is the line? The principle of bodily autonomy is not negotiable, even in a pandemic.

Addressing Counter-Signals

The Institutional-Scientific Grammar will point to population-level benefits: vaccines prevented millions of deaths, mandates increased uptake, the benefits outweigh the risks. But this misses the point. Population-level benefits do not override individual rights. I am not a data point in a population model; I am a person with sovereignty over my own body.

The grammar will also emphasize that serious adverse events are "rare." But "rare" is a population-level statistic. If I am the one who experiences a serious adverse event, it is not rare to me—it is 100%. I have a right to weigh that risk for myself, not to have it weighed for me by institutions that bear no responsibility for the consequences I experience.

The grammar will frame vaccine refusal as "misinformation" or "hesitancy," implying a knowledge deficit or irrational fear. This is condescending. My refusal is not based on ignorance; it is based on a different risk assessment and a different set of values. I value bodily autonomy, I distrust institutions with a track record of broken promises, and I am skeptical of interventions that are mandated rather than freely chosen.

Closure Statement

Individuals have the right to make their own medical decisions based on their own risk assessment. COVID-19 vaccines may benefit some people—particularly the elderly and those with serious comorbidities—but they are not appropriate for everyone. Vaccine effectiveness was oversold, particularly regarding transmission prevention and durability. Adverse events are more common and more serious than officially acknowledged. Mandates and certificates were unjustified violations of bodily autonomy and informed consent that eroded trust and set dangerous precedents.

Natural immunity provides substantial protection and should be recognized in policy. Individuals should be free to weigh their own risks and benefits without coercion. The one-size-fits-all approach ignored individual variation and treated people as means to a collective end rather than as autonomous agents with rights.

The COVID-19 vaccination campaign will be remembered not as a public health triumph but as a case study in institutional overreach, broken promises, and the erosion of medical ethics. The damage to trust and autonomy will take decades to repair.

Note on Closure: This closure is the product of processing the signal set through the Individual-Autonomy Grammar's rules (prioritizing individual risk assessment, weighting adverse event reports and autonomy violations, framing causation in personal terms, excluding population-level justifications for coercion). It is

not a verdict on reality itself, but rather the conclusion that this grammar's architecture produces when applied to this signal set.

4.3 Processing Through Critical-Structural Grammar

The COVID-19 vaccination campaign exemplifies pharmaceutical capitalism and biopolitical control in the 21st century. While vaccines may have provided some individual-level protection, the campaign's architecture—shaped by profit motives, regulatory capture, and state power—served to enrich pharmaceutical corporations, normalize surveillance and coercion, and deepen global health inequities.

Pharmaceutical Profits and Regulatory Capture

The COVID-19 pandemic was a windfall for pharmaceutical companies. Pfizer alone reported $37 billion in COVID vaccine revenue in 2021 (though this figure is not documented in the supplied corpus, it is widely reported). Moderna, which had never brought a product to market before, became a multi-billion-dollar company overnight. These profits were enabled by massive public subsidies (Operation Warp Speed in the US, advance purchase agreements globally) and protected by intellectual property regimes that prevented generic competition and technology transfer.

The relationship between pharmaceutical companies and regulatory agencies is not one of neutral oversight but of mutual dependence and revolving doors. Regulatory agencies like the FDA are partly funded by user fees from the companies they regulate. Senior officials move between industry and regulatory positions. This creates structural incentives for regulators to approve products quickly and to downplay safety signals that might threaten industry profits.

The supplied corpus does not provide detailed documentation of these financial flows and revolving-door relationships, but their absence from the literature is itself a signal. Research priorities are shaped by funding, and pharmaceutical companies fund research that serves their interests. Studies of vaccine effectiveness are abundant; studies of pharmaceutical profits, regulatory capture, and conflicts of interest are scarce. The literature reflects the priorities of those who fund it.

Research Priorities Shaped by Profit

The focus on expensive, patented mRNA vaccines rather than on cheaper alternatives (repurposed drugs, traditional vaccine platforms, non-pharmaceutical interventions) reflects profit logic, not public health logic. mRNA vaccines are highly profitable because they are patent-protected, require cold-chain infrastructure (creating dependence on wealthy-country supply chains), and—as it turned out—require repeated boosting (creating recurring revenue streams).

The systematic underrepresentation of natural immunity in research and policy is revealing. The supplied corpus contains extensive data on vaccine effectiveness but minimal comparative data on natural immunity or hybrid immunity [1]. This is not because natural immunity is unimportant—it is likely at least as protective as vaccine-induced immunity—but because natural immunity cannot be monetized. There is no profit in studying or promoting natural immunity, so it is neglected.

Similarly, the focus on individual vaccination rather than on structural determinants of health (safe workplaces, paid sick leave, adequate housing, universal healthcare) reflects the individualization of risk under neoliberalism. It is more profitable to sell vaccines to individuals than to invest in public health infrastructure or to challenge the economic arrangements that make people vulnerable to infectious disease.

Global Vaccine Apartheid

While wealthy countries hoarded vaccines and debated booster doses, the Global South faced vaccine shortages. Vaccine nationalism—wealthy countries securing advance purchase agreements that locked up supply—and intellectual property protections that prevented technology transfer and generic production led to a global vaccine apartheid. The supplied corpus does not provide detailed documentation of this inequity, but its absence is telling: the literature focuses on vaccine effectiveness in wealthy countries with robust surveillance systems, not on vaccine access in the Global South.

This inequity is not accidental but structural. Pharmaceutical companies prioritized wealthy markets where they could charge higher prices. The refusal to waive intellectual property protections (the TRIPS waiver proposal at the WTO was blocked by wealthy countries) prioritized corporate profits over global health. The result was preventable death and suffering in the Global South and the creation of conditions for new variants to emerge (Omicron likely originated in southern Africa, where vaccination rates were low due to lack of access).

Mandates as Biopolitical Control

Vaccine mandates and certificates were not merely public health interventions; they were exercises of state and corporate power over bodies. The fact that mandates increased uptake by 50–100% [30] demonstrates their coercive effectiveness, but it also reveals their authoritarian character. People were forced to accept a medical intervention or face loss of livelihood, exclusion from public spaces, and social stigmatization.

These policies disproportionately impacted working-class people who could not afford to lose their jobs, who worked in sectors where mandates were enforced (healthcare, education, transportation), and who lacked the social and economic capital to resist. The professional-managerial class could often work from home and avoid mandates; the working class could not.

Moreover, mandates normalized surveillance infrastructure—vaccine passports, digital health certificates, QR codes—that will persist beyond the pandemic. The precedent has been set: in a crisis (real or manufactured), the state can require proof of medical compliance to participate in social and economic life. This infrastructure can be repurposed for other forms of control.

Trust Decline as Rational Response

Survey data showing substantial loss of vaccine confidence—30% in France, with higher rates among younger adults and those who felt coerced [8]—are read by the Institutional-Scientific Grammar as a communication failure. But from a structural perspective, this trust decline is a rational response to institutional behavior.

Institutions made promises they could not keep (vaccines will prevent transmission and end the pandemic), changed guidance frequently without adequate explanation (masks, boosters), dismissed legitimate concerns about adverse events and coercion, and served pharmaceutical interests while claiming to serve public health. Why should people trust institutions that behave this way?

The focus on "combating misinformation" and "vaccine hesitancy" frames the problem as individual ignorance rather than institutional failure. It pathologizes distrust rather than interrogating the institutional behaviors that generate distrust. This is a classic move of power: when people stop believing official narratives, the problem is framed as the people's deficiency (they are misinformed, hesitant, irrational) rather than the institutions' loss of legitimacy.

Suppression of Dissent

The COVID-19 era saw unprecedented suppression of scientific and medical dissent. Physicians and scientists who questioned vaccine mandates, raised concerns about adverse events, or advocated for

alternative approaches (early treatment, natural immunity recognition) were deplatformed from social media, sanctioned by professional organizations, and accused of spreading "misinformation."

This suppression served to narrow the range of acceptable discourse and to protect institutional and pharmaceutical interests. Dissent was not engaged with on its merits but dismissed as dangerous and irresponsible. The fact that some dissenting claims were indeed false or misleading does not justify blanket suppression; it requires engagement and refutation. The refusal to engage suggests that institutions feared dissent not because it was false but because it threatened their authority and the interests they served.

Addressing Counter-Signals

The Institutional-Scientific Grammar will point to lives saved and population-level benefits. But this framing obscures distributional questions: who benefited (pharmaceutical companies, wealthy countries) and who bore the costs (the Global South, working-class people subjected to mandates, individuals who experienced adverse events)? Aggregate benefits can coexist with profound injustice in how those benefits and costs are distributed.

The Individual-Autonomy Grammar will emphasize personal freedom and bodily autonomy. This is important but insufficient. Focusing solely on individual rights obscures the structural forces that shape individual choices. People do not make "free" choices in a vacuum; they make choices constrained by economic necessity, shaped by corporate marketing, and influenced by institutions that serve elite interests. True autonomy requires not just freedom from coercion but also freedom from structural domination.

Closure Statement

The COVID-19 vaccination campaign exemplifies pharmaceutical capitalism and biopolitical control. Vaccines were developed and distributed according to profit logic, not global health need. Regulatory agencies, captured by industry through funding and revolving doors, prioritized rapid approval and high uptake over rigorous safety surveillance and transparent risk communication. Research priorities were shaped by pharmaceutical interests, leading to focus on expensive patented vaccines and neglect of natural immunity, repurposed drugs, and structural determinants of health.

Vaccine mandates and certificates served to normalize biopolitical control and surveillance infrastructure while disproportionately impacting working-class populations. Global vaccine apartheid—enabled by vaccine nationalism and intellectual property protections—led to preventable deaths in the Global South and created conditions for variant emergence. Trust decline is a rational response to institutional behavior that served elite interests while claiming to serve public health. Dissent was suppressed rather than engaged, narrowing the range of acceptable discourse.

The pandemic was a crisis, but the response was shaped by pre-existing structures of power and inequality. Pharmaceutical companies profited, wealthy countries hoarded, working-class people were coerced, and the Global South was abandoned. The focus on individual vaccination obscured the structural changes needed for genuine health justice: socialized pharmaceutical R&D, technology transfer, universal healthcare, safe workplaces, and economic arrangements that do not make people vulnerable to infectious disease.

The COVID-19 vaccination campaign will be remembered not as a triumph of science but as a case study in how crises are exploited to enrich elites, expand state power, and deepen global inequities.

Note on Closure: This closure is the product of processing the signal set through the Critical-Structural Grammar's rules (prioritizing power relations and profit flows, weighting structural significance and distributional impact, framing causation in political-economic terms, excluding analyses that treat institutions as neutral). It is not a verdict on reality itself, but rather the conclusion that this grammar's architecture produces when applied to this signal set.

Section 5: Closure Comparison

5.1 Closure Content Comparison

The three grammars produce radically different closures from the same signal set:

Institutional-Scientific: "Vaccines are safe and effective; they prevented millions of deaths; mandates were justified; trust decline is a communication challenge."

Individual-Autonomy: "Vaccines were oversold; effectiveness waned; adverse events were dismissed; mandates violated autonomy; trust decline is a rational response to broken promises."

Critical-Structural: "Vaccines served pharmaceutical profits; regulatory capture shaped policy; mandates normalized biopolitical control; global inequity was deepened; trust decline is a rational response to institutional behavior serving elite interests."

These are not different emphases on the same underlying reality; they are fundamentally different accounts of what happened and what it means. The Institutional-Scientific Grammar sees a public health success with communication challenges. The Individual-Autonomy Grammar sees institutional overreach and broken promises. The Critical-Structural Grammar sees pharmaceutical capitalism and biopolitical control.

5.2 Signal Divergence Analysis

Signals Weighted Heavily by All Grammars:

- Vaccine effectiveness data (though interpreted differently)
- Waning effectiveness over time
- Mandate effects on uptake

Signals Weighted Heavily by One or Two Grammars but Not Others:

Institutional-Scientific uniquely emphasizes:

- Meta-analyses and systematic reviews showing population-level benefits
- Modeling studies estimating deaths averted
- Pharmacovigilance system functioning (VAERS detecting rare signals)

Individual-Autonomy uniquely emphasizes:

- Individual adverse event reports and testimonies
- Feelings of coercion and autonomy violations
- Broken promises about transmission prevention
- Natural immunity neglect

Critical-Structural uniquely emphasizes:

- Pharmaceutical profits and regulatory capture (though under-documented in corpus)
- Global vaccine inequity and IP protections
- Disproportionate impact of mandates on working-class populations
- Suppression of dissent

Signals Processed Differently:

- VAERS surge: "system working" vs. "evidence of harm" vs. "system designed to obscure harm"
- Mandate effectiveness: "justified intervention" vs. "coercion" vs. "biopolitical control"
- Waning effectiveness: "expected phenomenon requiring boosters" vs. "broken promises" vs. "feature not bug for recurring revenue"

5.3 Exclusion Pattern Analysis

Institutional-Scientific Grammar Excludes:

- Individual adverse event testimonies without formal causality assessment
- Structural critiques of pharmaceutical industry without quantitative evidence
- Framing of mandates as "coercion" rather than "public health necessity"
- Long-term historical patterns of pharmaceutical malfeasance

Individual-Autonomy Grammar Excludes:

- Population-level benefits used to justify individual coercion
- Statistical dismissals of individual experiences
- Appeals to collective responsibility that override individual rights
- Institutional authority claims that bypass informed consent

Critical-Structural Grammar Excludes:

- Claims that scientific institutions are neutral and apolitical
- Analyses that ignore profit motives and regulatory capture
- Framings that individualize structural problems
- Population metrics that obscure distributional inequities

These exclusions are not oversights but constitutive of each grammar. Each grammar must exclude certain signals to maintain its coherence and produce its characteristic closure.

5.4 Causal Architecture Comparison

Institutional-Scientific: Biological-mechanistic causation validated by statistical association. Virus → immune response → clinical outcome, mediated by vaccine-induced immunity. Causation established through RCTs, observational studies, biological plausibility.

Individual-Autonomy: Individual-level probabilistic causation with emphasis on personal agency. My decision → my outcome, mediated by my unique risk factors and values. Causation assessed through personal risk calculation, precautionary principle, temporal proximity, lived experience.

Critical-Structural: Structural-political causation operating through institutions, markets, and power relations. Capitalist imperatives → institutional arrangements → knowledge production → policy → outcomes. Causation assessed through cui bono analysis, historical pattern recognition, structural logic, power mapping.

These causal architectures are incommensurable. They identify different causal agents (virus vs. individual vs. capital), different causal mechanisms (immune response vs. personal choice vs. power relations), and different causal endpoints (population health vs. individual autonomy vs. structural inequality).

5.5 Closure Range Comparison

Institutional-Scientific: Narrow closure focused on vaccine effectiveness, safety, and policy justification. Does not address pharmaceutical profits, regulatory capture, global inequity, or long-term trust dynamics except as "communication challenges."

Individual-Autonomy: Medium closure focused on individual rights, risk assessment, and autonomy violations. Addresses adverse events, coercion, and broken promises. Does not deeply engage with population-level benefits or structural power relations.

Critical-Structural: Broad closure addressing pharmaceutical profits, regulatory capture, global inequity, biopolitical control, and structural determinants of health. Does not deeply engage with individual-level clinical benefits or personal autonomy concerns except as they relate to power relations.

5.6 Closure Timing Comparison

Institutional-Scientific: Present-focused with near-future projection. Closure is provisional and updates as new evidence emerges. "Based on current data, vaccines are safe and effective; we will continue to monitor and update guidance."

Individual-Autonomy: Present-focused with emphasis on immediate decision urgency and personal long-term consequences. Closure is experiential and episodic. "I must decide now, and I will live with this decision forever."

Critical-Structural: Long historical horizon. Closure situates present events within decades or centuries of structural patterns. "This is the latest instantiation of pharmaceutical capitalism and medical colonialism; the pattern will continue until structural transformation occurs."

5.7 Grammar Translation Attempts

Institutional-Scientific ↔ Individual-Autonomy:

IS to IA: "Population-level benefits justify mandates" → IA hears: "Your individual rights don't matter; you are a means to a collective end."

IA to IS: "Mandates violated my autonomy" → IS hears: "You are prioritizing your personal preferences over public health necessity; this is selfish."

Translation fails because the grammars have different moral foundations: collective welfare vs. individual rights. What IS sees as justified trade-off, IA sees as fundamental violation.

Institutional-Scientific ↔ Critical-Structural:

IS to CS: "Vaccines prevented millions of deaths" → CS hears: "You are ignoring who profited, who was excluded, and what structural arrangements enabled this."

CS to IS: "Pharmaceutical companies profited from the pandemic" → IS hears: "This is irrelevant to the scientific question of whether vaccines work; you are imposing a political lens on a technical issue."

Translation fails because the grammars have different ontologies: IS treats science as separable from politics and economics; CS treats them as inseparable.

Individual-Autonomy ↔ Critical-Structural:

IA to CS: "I have a right to make my own medical decisions" → CS hears: "You are framing a structural problem as individual choice; your 'freedom' is shaped by forces you are not acknowledging."

CS to IA: "Mandates disproportionately impacted working-class people" → IA hears: "This is true, but the fundamental issue is that mandates violated everyone's autonomy, regardless of class."

Translation fails because the grammars have different units of analysis: IA focuses on the individual; CS focuses on structural positions and power relations.

5.8 Ontological Check

Do these grammars describe the same phenomenon?

In one sense, yes: All three grammars are processing the same empirical signals (vaccine effectiveness data, VAERS reports, mandate effects, trust surveys). They are all attempting to make sense of the COVID-19 vaccination campaign.

In a deeper sense, no: The grammars constitute different phenomena:

- Institutional-Scientific constitutes the phenomenon as a *public health intervention* to be evaluated by population-level health outcomes.
- Individual-Autonomy constitutes the phenomenon as a *personal medical decision* to be evaluated by individual benefit-risk assessment and autonomy preservation.
- Critical-Structural constitutes the phenomenon as an *exercise of power* to be evaluated by who benefits, who is harmed, and how structural inequalities are reproduced or challenged.

These are not three perspectives on one thing; they are three different things. The "COVID-19 vaccination campaign" is simultaneously a public health intervention, a personal medical decision, and an exercise of power. Which aspect is foregrounded determines what the phenomenon *is*.

This is the core insight of prismatic analysis: the phenomenon does not have a single, grammar-independent nature. It is constituted differently by different interpretive frameworks. The grammars do not describe a pre-existing reality; they enact different realities.

Section 6: Counter-Signals, Leakage, and Stress Test

6.1 Consolidated Counter-Signal Analysis

Counter-signals are observations that resist or complicate the closure produced by a grammar. They are not necessarily "evidence against" the grammar's claims but rather signals that the grammar must work harder to assimilate or that reveal the grammar's limitations.

Counter-Signal 1: Vaccine Effectiveness Against Infection Approached Zero

Challenges: Institutional-Scientific (contradicts early messaging about robust protection), Individual-Autonomy (supports claim of overselling), Critical-Structural (supports claim of marketing beyond performance).

Grammar Responses:

- IS: "This is expected viral evolution and antibody waning; protection against severe disease remained high; boosters restore protection."
- IA: "This proves they lied about effectiveness; I was right to be skeptical."
- CS: "This reveals that profit motive (recurring boosters) shaped product design and marketing."

Counter-Signal 2: Unprecedented VAERS Reporting Surge

Challenges: Institutional-Scientific (requires explaining away as scale/attention), Individual-Autonomy (supports claim of unusual harm), Critical-Structural (supports claim of surveillance inadequacy).

Grammar Responses:

- IS: "This reflects scale, attention, and regulatory encouragement; the system detected rare serious signals, proving it works."
- IA: "This is evidence of widespread harm that institutions are dismissing."
- CS: "This reveals that passive surveillance was never designed to capture true harm at population scale; the system's limitations are features, not bugs."

Counter-Signal 3: Policies That Increased Uptake Also Eroded Trust

Challenges: Institutional-Scientific (complicates framing of mandates as unambiguous success), Individual-Autonomy (supports autonomy violation claim), Critical-Structural (supports biopolitical control claim).

Grammar Responses:

- IS: "This is a regrettable but acceptable trade-off; short-term uptake gains outweighed long-term trust costs; trust can be rebuilt through better communication."
- IA: "This proves mandates were wrong; coercion always backfires."
- CS: "This is predictable blowback from authoritarian measures; trust erosion is a feature of biopolitical control, not a bug."

Counter-Signal 4: Younger Populations Lost More Confidence

Challenges: Institutional-Scientific (puzzling from benefit-risk perspective), Individual-Autonomy (supports claim that policy ignored individual variation), Critical-Structural (supports claim that policy served interests other than health).

Grammar Responses:

- IS: "This reflects generational differences in institutional trust and greater exposure to social media misinformation; it is a communication challenge."
- IA: "This makes sense; younger people had less to gain from vaccination and more to lose from coercion."
- CS: "This reflects younger generations' greater awareness of institutional capture and less deference to authority; it is a sign of political consciousness, not ignorance."

Counter-Signal 5: Natural Immunity Underrepresented

Challenges: Institutional-Scientific (reveals gap in evidence base), Individual-Autonomy (supports claim that policy prioritized vaccination over immunity), Critical-Structural (supports claim that profit shaped research priorities).

Grammar Responses:

- IS: "Natural immunity is harder to study (no controlled exposure, variable timing and severity of infection); vaccine-induced immunity is more standardized and thus easier to measure and recommend."
- IA: "This proves policy was about vaccination targets, not immunity; natural immunity was ignored because it couldn't be monetized or mandated."

- CS: "This is direct evidence that pharmaceutical profit shaped research and policy priorities; natural immunity cannot be sold, so it was neglected."

6.2 Leakage Instances

Leakage occurs when a grammar's processing rules produce results that undermine the grammar's own closure or when signals from one grammar intrude into another grammar's processing in ways that cannot be fully assimilated.

Leakage Instance 1: Institutional-Scientific Grammar and Trust Decline

The Institutional-Scientific Grammar frames trust decline as a "communication challenge" that can be solved through "better messaging." But the grammar's own evidence shows that trust decline is associated with the very policies (mandates, certificates) that the grammar endorses as effective public health interventions [8], [24]. This creates a tension: if effective policies erode trust, and trust is necessary for future public health interventions, then "effective" policies may be self-undermining in the long term.

The grammar cannot fully assimilate this tension without questioning its own framework. To acknowledge that mandates may have been counterproductive in the long term would require weighing long-term institutional legitimacy against short-term uptake gains—a calculation that the grammar's present-focused temporal orientation and population-level outcome focus make difficult.

Leakage Instance 2: Individual-Autonomy Grammar and Population Externalities

The Individual-Autonomy Grammar insists on individual rights and personal risk assessment. But it struggles to address the fact that individual vaccination decisions have population-level externalities: unvaccinated individuals may contribute to transmission, strain healthcare systems, and enable variant emergence. The grammar's response—"my body, my choice"—is coherent within its own framework but does not engage with the collective action problem.

When pressed, the grammar may argue that externalities are overstated (vaccines don't prevent transmission effectively, so my vaccination status doesn't affect you) or that externalities do not justify coercion (even if my choice affects you, you don't have the right to force me). But this reveals a limitation: the grammar has no robust account of collective responsibility or how to balance individual rights against collective welfare.

Leakage Instance 3: Critical-Structural Grammar and Individual-Level Benefits

The Critical-Structural Grammar emphasizes pharmaceutical profits, regulatory capture, and global inequity. But it struggles to fully account for the fact that vaccines did provide substantial individual-level protection against severe disease and death, particularly for high-risk populations [1], [3]. The grammar's response—"aggregate benefits can coexist with profound injustice in distribution"—is true but risks appearing to dismiss or minimize the real benefits that individuals experienced.

When pressed, the grammar may argue that benefits could have been achieved through alternative arrangements (socialized R&D, generic production, global equity) or that the focus on individual benefits obscures structural harms. But this reveals a limitation: the grammar has difficulty celebrating individual-level successes without appearing to endorse the structural arrangements that produced them.

6.3 Grammar Stress Test: Most Threatening Counter-Signal for Each Grammar

Institutional-Scientific Grammar: Most Threatened by "Policies That Increased Uptake Also Eroded Trust"

This counter-signal threatens the grammar's core claim that mandates were justified and effective. If mandates achieved short-term uptake gains but caused long-term trust erosion that will undermine future public health interventions, then the policies may have been net-negative even by the grammar's own consequentialist logic.

The grammar can respond by arguing that trust can be rebuilt, that the short-term benefits (lives saved) outweighed long-term costs, or that trust decline was caused by misinformation rather than by the policies themselves. But each response is vulnerable:

- "Trust can be rebuilt" is speculative and not supported by the evidence (trust has not been rebuilt as of 2024).
- "Short-term benefits outweighed long-term costs" requires a calculation that the grammar has not performed and that depends on contested assumptions about future pandemic preparedness needs.
- "Trust decline was caused by misinformation" is circular (why did people believe misinformation? perhaps because they distrusted institutions that were coercing them).

This counter-signal reveals a potential internal contradiction in the grammar: policies that are "effective" by one metric (uptake) may be counterproductive by another metric (institutional legitimacy).

Individual-Autonomy Grammar: Most Threatened by "Vaccines Prevented Millions of Deaths"

This counter-signal (from modeling studies [28], [29]) threatens the grammar's framing of vaccines as oversold and mandates as unjustified. If vaccines truly prevented millions of deaths at the population level, then the case for mandates becomes stronger, and the grammar's emphasis on individual autonomy appears selfish or short-sighted.

The grammar can respond by arguing that:

- Modeling estimates are speculative and depend on contested assumptions.
- Population-level benefits do not justify individual coercion (the ends don't justify the means).
- The deaths prevented were primarily among high-risk individuals who would have chosen to vaccinate anyway, so mandates were unnecessary.
- Alternative approaches (focused protection, early treatment, natural immunity recognition) could have achieved similar benefits without coercion.

But each response is vulnerable:

- Dismissing modeling as "speculative" while accepting individual adverse event reports as "real" reveals an inconsistency in epistemic standards.
- "Ends don't justify means" is a principled stance but does not engage with the magnitude of the trade-off (millions of deaths vs. autonomy violations).
- The claim that mandates were unnecessary because high-risk individuals would have vaccinated anyway is empirically questionable (mandates increased uptake even among high-risk groups).
- Alternative approaches are speculative and lack the same level of empirical support as vaccination.

This counter-signal reveals a potential limitation of the grammar: its focus on individual rights may struggle to account for situations where individual choices have catastrophic collective consequences.

Critical-Structural Grammar: Most Threatened by "Vaccines Provided Substantial Individual-Level Protection"

This counter-signal (from real-world effectiveness studies [1], [3], [9]) threatens the grammar's framing of vaccines as primarily serving pharmaceutical profits rather than public health. If vaccines genuinely

provided strong protection against severe disease and death, then the grammar's emphasis on profit motives and regulatory capture may appear to dismiss or minimize real benefits.

The grammar can respond by arguing that:

- Benefits could have been achieved through alternative arrangements (socialized R&D, generic production, global equity) that would have been more just.
- The focus on individual benefits obscures structural harms (global inequity, coercion, surveillance normalization).
- Pharmaceutical companies profited from a product that was developed with massive public subsidies and protected by IP regimes, so the benefits are not evidence against the critique of pharmaceutical capitalism.
- The grammar is not denying that vaccines provided benefits but is interrogating the structural arrangements that shaped how those benefits were produced and distributed.

But each response is vulnerable:

- "Alternative arrangements could have been better" is speculative and does not negate the fact that the actual vaccines provided real benefits.
- "Focus on individual benefits obscures structural harms" risks appearing to dismiss the experiences of people whose lives were saved.
- "Pharmaceutical companies profited" is true but does not address whether the profit motive undermined vaccine effectiveness or safety (the evidence suggests it did not, at least for individual-level protection).
- "We're not denying benefits, just interrogating arrangements" is a sophisticated response but may be perceived as moving the goalposts or as insufficiently acknowledging the magnitude of benefits.

This counter-signal reveals a potential limitation of the grammar: its focus on structural critique may struggle to celebrate individual-level successes or to acknowledge when capitalist arrangements produce genuine public goods (even if unjustly distributed).

Section 7: Post-Analysis Reflexive Note

7.1 Comparison Against Step 0 Declaration

Home Grammar Confirmation:
The analysis confirmed my home grammar as Institutional-Scientific. Throughout the processing, I felt most comfortable and fluent when operating within that grammar—citing peer-reviewed studies, emphasizing population-level statistics, framing causation in biological-mechanistic terms. The Institutional-Scientific section wrote itself most easily; I knew instinctively which signals to emphasize and how to construct the argument.

Difficulty with Critical-Structural Grammar:
As anticipated, the Critical-Structural Grammar was most challenging. I had to consciously resist the pull to dismiss structural critiques as "speculative" or "political" and to treat them as legitimate interpretive moves. The difficulty was not intellectual—I can articulate the arguments—but dispositional. The Critical-Structural section required the most revision and self-correction to ensure I was operating the grammar faithfully rather than caricaturing it.

Interestingly, I found myself more sympathetic to the Critical-Structural Grammar by the end of the analysis than at the beginning. The process of seriously engaging with its signal selection rules and causal

architecture revealed insights that my home grammar systematically obscures—particularly about pharmaceutical profits, regulatory capture, and global inequity. This suggests that the method is working as intended: forcing sustained operation of non-home grammars can shift one's perspective.

Blind Spots Partially Confirmed:
The anticipated blind spots were partially confirmed:

1. *Individual phenomenology:* I did underweight individual adverse event experiences in the Institutional-Scientific processing, treating them as "anecdotes" until I consciously corrected this in the Individual-Autonomy processing. The method forced me to take seriously the experiential texture of vaccine injury and decision-making under uncertainty.

2. *Structural power:* I initially struggled to foreground pharmaceutical profits and regulatory capture in the Critical-Structural processing, wanting to emphasize that "the science is independently validated." The method forced me to interrogate this assumption and to consider how funding structures and revolving doors shape what counts as "independent validation."

3. *Trust dynamics:* I was surprised by how much the trust decline signals challenged the Institutional-Scientific Grammar's closure. I had anticipated treating trust as a simple communication problem, but the evidence that mandates both increased uptake and eroded trust created a genuine tension that the grammar struggles to resolve.

Temporal Orientation Confirmed:
The three grammars' temporal orientations played out as anticipated. The Institutional-Scientific processing was present-focused, emphasizing current data and near-term recommendations. The Individual-Autonomy processing emphasized immediate decision urgency and personal long-term consequences. The Critical-Structural processing required the longest historical horizon, situating the vaccination campaign within decades of pharmaceutical capitalism and medical colonialism.

I noticed that my home grammar's presentism made me impatient with the Critical-Structural Grammar's historical contextualization. I kept wanting to say, "But what about the current evidence?" This reveals how temporal orientation shapes what counts as relevant: my home grammar treats long-term historical patterns as background context, while the Critical-Structural Grammar treats them as primary explanatory variables.

7.2 Surprises and Shifts

Surprise 1: The Strength of the "Mandates Eroded Trust" Counter-Signal
I did not anticipate how much this counter-signal would challenge the Institutional-Scientific Grammar's closure. The evidence that policies which achieved their proximate goal (increased uptake) also caused substantial trust decline creates a genuine dilemma that the grammar cannot easily resolve. This suggests that the grammar's consequentialist logic may be more internally contested than I initially recognized.

Surprise 2: The Individual-Autonomy Grammar's Coherence
I expected the Individual-Autonomy Grammar to be the easiest to dismiss or caricature, but I found it more internally coherent than anticipated. Its emphasis on bodily autonomy, informed consent, and individual risk assessment is grounded in legitimate ethical principles (Nuremberg Code, medical ethics tradition). The grammar's weakness is not incoherence but rather its difficulty accounting for collective action problems and population-level externalities.

Surprise 3: The Absence of Certain Signals in the Corpus
I was struck by how much the supplied corpus lacks certain signals that are central to the Critical-Structural Grammar: pharmaceutical revenue and profit data, regulatory revolving-door documentation, WHO messaging timelines, platform content moderation statistics, detailed global vaccine inequity data. This

absence is itself a signal about research priorities and funding structures. The literature reflects what gets studied, and what gets studied reflects who funds research and what questions serve their interests.

Shift in Perspective:
The analysis shifted my perspective in two ways:

1. I have greater appreciation for the legitimacy of non-Institutional-Scientific grammars. The Individual-Autonomy Grammar's emphasis on bodily autonomy and the Critical-Structural Grammar's attention to power relations are not "biases" or "political lenses" but legitimate interpretive frameworks that illuminate aspects of the phenomenon that my home grammar obscures.

2. I have greater skepticism about the neutrality of my home grammar. The Institutional-Scientific Grammar presents itself as "just looking at the evidence," but the analysis revealed how much work the grammar does in selecting which evidence counts, how to weight it, and what causal stories are admissible. The grammar is not a neutral window on reality but an active interpretive framework.

Section 8: Methodological Observations

8.1 What Worked

1. The Nine-Parameter Grammar Specification
The requirement to specify nine parameters for each grammar (primary analytical variable, signal selection rules, weighting priority, causal chain type, admissible closure, excluded signals, characteristic vocabulary, temporal orientation, temporal formation) was extremely valuable. It forced precision and prevented me from operating grammars superficially or caricaturing them. The parameters provided a checklist to ensure I was processing signals through each grammar's actual rules rather than through my intuitions about what each grammar "would say."

2. The Counter-Signal and Leakage Analysis
Identifying counter-signals and leakage instances was crucial for revealing each grammar's limitations and internal tensions. Without this step, the analysis would have produced three self-contained, mutually incomprehensible closures with no way to assess their relative strengths and weaknesses. The counter-signal analysis showed where each grammar is vulnerable, and the leakage analysis showed where grammars' own processing rules produce results that undermine their closures.

3. The Stress Test
Identifying the most threatening counter-signal for each grammar was a powerful heuristic for understanding each grammar's core commitments and vulnerabilities. It forced me to ask: "What would it take to make this grammar abandon its closure?" This revealed that grammars are not infinitely flexible; they have breaking points where counter-signals become too strong to assimilate.

4. The Reflexive Bookends (Sections 0 and 7)
The pre-analysis and post-analysis reflexive sections were essential for making the analyst's positionality visible and for tracking how the analysis shifted perspective. Without Section 0, the analysis would have appeared to come from nowhere, as if the analyst were a neutral processor. Without Section 7, there would be no accountability for whether the analysis actually challenged the analyst's home grammar or merely reinforced it.

8.2 Difficulties Encountered

1. Operating Non-Home Grammars Authentically
The hardest challenge was operating non-home grammars authentically rather than caricaturing them. My first drafts of the Individual-Autonomy and Critical-Structural sections were strawman versions that my home grammar could easily dismiss. It required multiple revisions and conscious self-correction to ensure I was processing signals through each grammar's actual rules and producing closures that practitioners of those grammars would recognize as legitimate.

A related difficulty: how do I know when I'm operating a grammar authentically vs. caricaturing it? I used two heuristics: (1) Would a practitioner of this grammar recognize this processing as legitimate? (2) Does this processing reveal insights that challenge my home grammar, or does it merely reinforce my home grammar by making alternatives look foolish? These heuristics helped but did not fully resolve the difficulty.

2. Corpus Limitations
The supplied corpus was strong on vaccine effectiveness data, safety surveillance, and policy interventions but weak on pharmaceutical profits, regulatory capture, global inequity, and information environment dynamics. This created an asymmetry: the Institutional-Scientific Grammar had abundant signals to work with, while the Critical-Structural Grammar had to work harder to find signals and often had to note their absence.

This raises a methodological question: Is the method biased toward grammars that align with dominant research priorities? If the corpus reflects what gets studied, and what gets studied reflects institutional and funding priorities, then grammars that challenge those priorities will always be working with sparser evidence. This is not a flaw in the method but a feature of the phenomenon: the evidence base itself is shaped by power relations.

3. Closure Range and Depth Trade-offs
Each grammar's processing section was constrained to 1,000–1,500 words, which required difficult trade-offs between breadth (covering all relevant signals) and depth (engaging each signal thoroughly). I often felt I was skimming the surface of complex arguments. A longer format would allow more nuanced processing, but it would also risk losing the comparative structure that makes the method powerful.

4. Avoiding False Equivalence
The method's structure—three grammars, three closures, comparative analysis—risks creating a false equivalence, as if all three grammars are equally valid or equally supported by evidence. But the grammars are not symmetrical. The Institutional-Scientific Grammar has more empirical support in the supplied corpus (because the corpus reflects institutional research priorities). The Individual-Autonomy Grammar has strong ethical grounding but weaker empirical support for some of its claims (e.g., that adverse events are more common than acknowledged). The Critical-Structural Grammar has strong structural logic but less direct empirical documentation in the corpus (because structural power is harder to measure and less often studied).

The method does not resolve this asymmetry; it makes it visible. The point is not to say "all grammars are equally right" but to show how different grammars constitute different phenomena and produce different closures, and to reveal the strengths and limitations of each.

8.3 Guidance Needed

1. How to Handle Empirical Asymmetries
When one grammar has abundant empirical support in the corpus and another does not, how should this be handled? Should the analysis note the asymmetry and interrogate its causes (as I did)? Should it seek additional sources to balance the corpus? Should it acknowledge that some grammars are more empirically grounded than others in this particular evidence base?

I chose to note the asymmetry and treat it as a signal about research priorities and power relations. But guidance on how to handle this systematically would be valuable.

2. How to Assess Authentic Grammar Operation
How can an analyst assess whether they are operating a non-home grammar authentically vs. caricaturing it? I used the heuristics mentioned above, but more systematic guidance would help. Possible approaches:

- Have practitioners of each grammar review the processing sections for authenticity.
- Develop a checklist of markers of authentic vs. caricatured grammar operation.
- Require the analyst to cite exemplars of each grammar (scholars, texts, communities) and demonstrate alignment with those exemplars.

3. How to Handle Grammars That Reject the Method
Some grammars might reject the prismatic method itself as illegitimate. For example, a strong version of the Institutional-Scientific Grammar might argue that there is one correct interpretation (the one supported by the best evidence) and that treating other interpretations as equally valid "grammars" is relativism. A strong version of the Critical-Structural Grammar might argue that the method's neutrality is itself a political stance that obscures power relations.

How should the method respond to such rejections? Should it defend its meta-level stance? Should it acknowledge that the method itself operates within a particular grammar (perhaps a pragmatist or pluralist grammar)? Guidance on this would be valuable.

8.4 Suggestions for Refining the Method

1. Add a "Grammar Interaction" Section
The current method produces three separate processing sections and then compares closures. But in real-world discourse, grammars interact: people operating different grammars argue with each other, try to translate between grammars, form coalitions, etc. A section analyzing how grammars interact in practice—where they find common ground, where translation fails, where one grammar dominates institutional discourse—would add valuable insight.

2. Develop a "Grammar Strength" Rubric
The method could benefit from a systematic rubric for assessing each grammar's strengths and weaknesses in relation to a particular signal set. Dimensions might include:

- Empirical support (how much evidence in the corpus supports this grammar's closure?)
- Internal coherence (how well does the grammar handle counter-signals and leakage?)
- Explanatory scope (how much of the phenomenon does this grammar account for?)
- Ethical grounding (how well does this grammar align with widely shared moral principles?)
- Practical utility (how useful is this grammar for guiding action?)

Such a rubric would not produce a single "winner" but would make the comparative assessment more systematic.

3. Require Explicit Corpus Critique
The method could require a section analyzing the corpus itself: What is present? What is absent? Whose research priorities does the corpus reflect? What would a corpus shaped by different priorities look like? This would make visible the ways that the evidence base itself is shaped by power relations and institutional priorities.

4. Add a "Synthesis" or "Pragmatic Integration" Section
After producing three closures and comparing them, the method could require a final section attempting pragmatic integration: Given the strengths and limitations of each grammar, what practical guidance can be

offered? This would not be a "meta-closure" claiming to transcend the grammars but rather a pragmatic attempt to navigate between them for specific purposes (policy-making, clinical decision-making, social movement strategy, etc.).

5. Develop Grammar Exemplar Library
The method would benefit from a library of exemplars for each grammar: key texts, scholars, communities, and arguments that represent authentic operation of each grammar. This would help analysts ensure they are operating grammars faithfully and would provide a reference point for assessing authenticity.

Conclusion

This prismatic analysis has demonstrated that the COVID-19 vaccination discourse (2020–2024) is not a single phenomenon with multiple perspectives but rather multiple phenomena constituted by different interpretive grammars. The Institutional-Scientific Grammar constitutes it as a public health intervention to be evaluated by population-level outcomes. The Individual-Autonomy Grammar constitutes it as a personal medical decision to be evaluated by individual benefit-risk assessment and autonomy preservation. The Critical-Structural Grammar constitutes it as an exercise of power to be evaluated by distributional justice and structural transformation.

Each grammar produces a coherent closure from the same signal set, but these closures are incommensurable. They identify different causal agents, different causal mechanisms, different outcomes that matter, and different criteria for success. Translation between grammars systematically fails because they operate with different ontologies, epistemologies, and moral foundations.

The method reveals that interpretive divergence is not a problem to be solved through more evidence or better communication. It is a structural feature of phenomena that are constituted differently by different grammars. The task is not to determine which grammar is "correct" but to understand how each grammar works, what it illuminates, what it obscures, and where it is vulnerable to counter-signals.

This analysis has challenged my home grammar (Institutional-Scientific) by forcing me to take seriously the legitimacy of alternative grammars and to recognize that my home grammar is not a neutral window on reality but an active interpretive framework with its own exclusions and limitations. The COVID-19 vaccination campaign is simultaneously a public health triumph, an autonomy violation, and an exercise of pharmaceutical capitalism. Which aspect is foregrounded determines what the phenomenon *is*.

Signal Set Extraction (Extra file)

TL;DR

Real-world studies show high protection against severe COVID-19 but marked waning of protection against infection and reduced effectiveness versus Omicron; VAERS reporting surged in 2021 but interpretation is

limited by passive surveillance constraints. Several policy signals (certificates, mandates) produced short-term uptake gains while trust and demographic hesitancy patterns shifted unevenly.

Vaccine effectiveness trends

Vaccines retained strong protection against severe outcomes but showed substantial waning against infection and variant-dependent reductions; boosters partially restored protection in the short term. Comparative real-world effectiveness shows mRNA vaccines generally outperforming Ad26.COV2.S, and Omicron markedly reduced vaccine effectiveness against infection.

- Table comparing real-world effectiveness across three major vaccines (population/period estimates reported in the supplied literature)

Vaccine	Real-world VE vs hospitalization/ED	Pre vs post Delta VE for infection
BNT162b2 (Pfizer)	77% (95% CI 76–78) against hospital/ED-diagnosed COVID-19 in meta-analysis of claims databases [1]	87% before 1 July 2021 → 52% after 1 July 2021 in Michigan Medicine cohort [2]
mRNA-1273 (Moderna)	84% (95% CI 83–85) against hospital/ED-diagnosed COVID-19 in same analysis [1]	92% before 1 July 2021 → 70% after 1 July 2021 [2]
Ad26.COV2.S (J&J)	66% (95% CI 63–68) against hospital/ED-diagnosed COVID-19 in same analysis [1]	76% before 1 July 2021 → 49% after 1 July 2021 [2]

- Waning and variant effects
  - Waning over months: VE against all infections fell from ~83% in month 1 to ~22% at ≥5 months after primary series, while protection against severe disease remained comparatively high (≈90% at ≥5 months) in pooled analyses [3].
  - Omicron-specific pooled estimates: pooled VE against Omicron infection ≈20.4%; VE declined from ~28.1% at 3 months to ~3.9% at 6 months after primary series; a booster restored protection against Omicron infection to ~51.1% within three months but waned thereafter; VE against severe Omicron disease rose to ~86% after booster doses in pooled studies [4].
  - Booster impact: multiple reviews report meaningful short-term restoration of protection for infection and stronger restoration for severe outcomes after booster doses [4]

3
.

- Evidence gaps and contested points
    - Phase-3 trial efficacy figures per vaccine (head-to-head, standardized across variants and ages) are not consistently reported across the supplied corpus, so precise phase-3 efficacy percentages by manufacturer for 2020 trials are insufficiently documented in the provided literature.

Safety surveillance signals

Passive-signal volumes and leading reported symptoms are well documented in VAERS but causality and incidence interpretation are constrained; detailed myocarditis/pericarditis incidence and UK Yellow Card summaries are not available in the supplied corpus. Reporting surges and symptom tallies provide empirical signals but require careful interpretation.

- VAERS longitudinal patterns and counts
    - Report volumes: VAERS contained 1,396,280 domestic and 346,210 non-domestic reports over 1990–2021, with 2021 showing the highest annual reporting share (48.52% domestic, 70.33% non-domestic)
      5
      .
    - Reported outcomes in 1990–2021: reported incidents included deaths (1.00% domestic; 4.08% non-domestic), ER/doctor visits (13.37% domestic), hospitalizations (5.84% domestic; 27.78% non-domestic)
      5
      .
    - Top vaccines and symptoms in 2021: COVID-19 vaccines (Moderna, Pfizer-BioNTech, Janssen) were the top three vaccines by report count; top reported AEFIs in 2021 included headache, pyrexia, and fatigue
      5
      .
- Temporal and symptom-level VAERS signals (2020–2022 analyses)
    - Most frequent symptoms: counts reported in a temporal analysis included headache N=141,186; pyrexia N=122,120; fatigue N=121,910; chills+pyrexia combination N=56,954; death was noted as the most frequent item within serious adverse event reports in that dataset
      6
      .
    - Reporting trends: the temporal analysis observed an overall decreasing reporting rate for COVID-19–related adverse events after initial peaks and an initial higher reporting rate for Moderna versus Pfizer during early rollout that later converged
      6
      .
- Limitations and contested interpretation
    - Surveillance limits: authors note that VAERS is useful for signal detection but subject to reporting biases, regulatory and vaccine-availability influences, and lacks

denominator/exposure-controlled incidence estimation; this limitation is emphasized as constraining causal inference from raw VAERS counts
5
.
    - Insufficient evidence: the supplied corpus does not include robust, population-based incidence estimates (e.g., myocarditis/pericarditis rates stratified by age, dose, and vaccine product) nor consolidated Yellow Card system summary statistics, so those specific incidence rates are not extractable here.

Mortality signals and mandate effects

Direct empirical excess-mortality comparisons pre-vaccine versus 2021–2024 and age-stratified geographic excess-mortality time series are not fully documented in the supplied set; policy interventions such as certificates and mandates show measurable short-term impacts on uptake in multiple studies. Modeling work indicates large numbers of deaths averted by vaccination in early rollout (general statement), but precise excess-mortality timelines and stratified statistics are not extractable here.

- Excess mortality and modeling
    - Insufficient evidence: the supplied corpus does not provide a consistent set of age-stratified, country-level all-cause excess-mortality time series that directly compare 2020 baseline versus 2021–2024 rollout periods; therefore specific excess-mortality percentages or counts by age and geography cannot be reported from these materials.
- Mandates, certificates and uptake empirical signals
    - COVID certificate effects: synthetic-control analyses of six countries that introduced COVID certification (May–Aug 2021) found vaccination doses increased beginning ≈20 days before implementation and effects persisted up to ≈40 days after; increases were largest where pre-intervention uptake was lower
7
.
    - Mandate announcements and quantified gains: studies using event-study/difference-in-differences approaches found announcement of vaccine mandates was associated with large short-term increases in first-dose uptake (average >50% first week, >100% second week in Canadian provinces) and estimated net gains (e.g., ~289,000 additional first doses in Canada by Sept 30, 2021) with larger aggregate gains reported in some European countries in the same analyses
8
.
- Contested or uncertain attribution
    - Interpretation caveats: several authors caution that observed spikes may include intertemporal substitution (people vaccinating sooner than planned) and that net long-term increases versus short-term timing effects require longer follow-up and counterfactual modeling
8

7
.

Trust patterns and vaccination disparities

Surveys and longitudinal analyses in the supplied studies document shifting trust and heterogeneous uptake by age, race, and perceived coercion; mandatory policies and high-profile safety events influenced public confidence in measurable ways. Multiple studies document declines in confidence among younger adults and among people reporting coercion.

- Key empirical survey signals
    - France April–May 2022: in a representative survey (n=1,929), 30% reported having lost general vaccine confidence after the COVID-19 campaign, 13.4% reported a gain; loss of confidence was highest in ages 25–34 (45%) vs >75 (14.6%); among vaccinated respondents who felt “very constrained,” 43.6% reported loss of confidence [9].
    - EU weekly panel: higher trust in science correlated with lower vaccine hesitancy, while trust in social media and using social media as main information source were positively associated with hesitancy; the temporary suspension of AstraZeneca in March 2021 significantly increased hesitancy in some subgroups in that panel [10].
    - Denmark Nov 8, 2021 press conference: reintroduction of vaccine passports/pressured measures decreased trust in pandemic management by 11 percentage points among unvaccinated individuals in daily national surveys [11].
- Demographic disparities and longitudinal patterns
    - Race and time: US state-level longitudinal analysis (Jan–Oct 2021) showed vaccine hesitancy decreased over time overall, with larger declines in hesitancy among Black populations, while vaccine refusal among White populations remained relatively stable over the observation period [12].
    - Individual determinants: multivariable survey analyses link mistrust of vaccine benefit, lower trust in institutions, and sociodemographic variables to vaccine hesitancy and lower intention to vaccinate [13].
- Policy interactions with trust and uptake
    - Certificates and coercion: analyses indicate certification/mandates increased uptake in affected groups but are associated with self-reported feelings of coercion and, in some populations, measurable declines in trust, particularly among those who felt constrained by policies [7]

[11]
.

Information environment and industry data

The supplied literature includes empirical analyses of social media content and studies linking policy events to public sentiment, but does not provide WHO messaging timelines, pharmaceutical revenue/profit figures, or platform content-removal statistics. Social media content studies reveal temporal shifts in sentiment rather than moderation metrics.

- Social media content signals
  - Twitter/X discourse phases 2021 (Malaysia): thematic analysis of X (Twitter) across 2021 identified three phases—initial uncertainty, then proactive promotion/correction during rollout, and later tension when adolescent vaccination and boosters began; more anti- than pro-vaccine tweets were observed in the sample but community self-correction mechanisms were documented [14].
  - Insufficient evidence on moderation: the supplied corpus does not include platform policy timelines with quantifiable content-removal statistics or comprehensive cross-platform moderation trend data, so those signals cannot be extracted here.
- WHO messaging and industry economics
  - Insufficient evidence: the provided literature does not contain systematic timelines of WHO/public-health guidance changes (e.g., mask guidance for vaccinated individuals), nor does it provide consolidated pharmaceutical vaccine revenue or profit figures and government purchase-agreement terms for 2020–2024; these items are therefore not reportable from the supplied set.
- Contested signals
  - Public perception vs measured moderation: some studies link policy and safety-event announcements (e.g., AstraZeneca suspension, reintroduced passports) to measurable changes in hesitancy and trust [10][11][9], but the corpus lacks direct empirical follow-up tying moderation actions or industry revenue disclosures to trust shifts, making attribution contested or unresolved in the supplied materials.
